SUBJECT INDEX

A

Abortion. Aberrant Karyotypes and Spontaneous — in a Japanese Family (Tetsuji Kadotani, Koso Ohama, Toshio Sofuni and Howard B. Hamilton), 735
Abortion by Prostaglandin Injection, *news*, 415
Abortion Law, Amendment, *news*, 676
Abortion Statistics, *news*, 579
Abortion Test, *news*, 691
Abscission. Ethylene, the Natural Regulator of Leaf — (Michael B. Jackson and Daphne J. Osborne), 1019
Academic Village, USSR, *news*, 782
Acanthaster Disaster (Lowell P. Thomas), *correspondence*, 1269
Accelerator, Bubble Chamber, Mirabelle, *news*, 127
Accelerator, CERN, *news*, 491
Acetylcholine. Complexes between — and Catecholamines and their Tolerance to Mental Illness (Lauro Galzigna), 1058
  Interaction of — with Different Cholinergic Nerve Receptors (Cyrus Chothia), 36
Acetylcholinesterase. Localization of — by Immunofluorescence in Eel Electroplax (Philippe Benda, Shigeru Tsuji, Jean Daussant and Jean-Pierre Changeux), 1149
Achene. — Spacing of Strawberries as an Aid to calculating Potential Yield (A. J. Abbott and R. W. Webb), 663
Acoustics. — Basis for Individual Recognition by Voice in the Gannet (Sheila J. White, R. E. C. White and W. H. Thorpe), 1156
Actinomycin *D*: —: Effects on Memory at Different Times after Training (Larry R. Squire and Samuel H. Barondes), 649
  Effects of — and Cycloheximide on RNA and Protein Synthesis in Cleavage Stage Mouse Embryos (Richard J. Tasca and Nina Hillman), 1022
  Effect of Cycloheximide and — on the Behaviour of the Headless Cockroach (E. Glassman, A. Henderson, M. Cordle, H. M. Moon and J. E. Wilson), 967
Activity Periodicity. Cyclical "On Demand" Oral Intake by Adults (Ian Oswald, Judith Merrington and Heather Lewis), 959
Adenosine Phosphates. Non-enzymatic Hydrolysis of — (H. R. Hulett), 1248
Adenosine Triphosphate. Three Dimensional Structure of — (Olga Kennard, N. W. Isaacs, J. C. Coppola, A. J. Kirby, Stuart Warren, W. D. S. Motherwell, D. G. Watson, D. L. Wampler, D. H. Chenery, A. C. Larson, K. Ann Kerr and L. Riva di Sanseberine), 333
Adenoviruses. Effects of — on the Chromosomes of Normal Human Cells and Cells Trisomic for an *E* Chromosome (J. K. McDougall), 456
Adjuvants. Effect of — on the Immunosuppressive Properties of Antilymphocytic Globulin (Randall A. Allardyce, Robert D. Hunter and Keith James), 1141
Adrenal. Effect of Foetal Hypophysectomy on Catecholamine Levels in Lamb — during Prolonged Gestation (R. S. Comline, Marian Silver and I. A. Silver), 739
Adrenaline. Changes in Enzymes involved in the Biosynthesis and Metabolism of Noradrenaline and — after Psychosocial Stimulation (Julius Axelrod, Robert A. Mueller, James P. Henry and Patricia M. Stephens), 1059
AEC and Nuclear Research, *news*, 684
AEC Finance, *news*, 582
Aflatoxin B_1. Acute Toxicity of — in Wethers (Bernard H. Armbrecht, William T. Shalkop, Larry D. Rollins, Albert E. Pohland and Leonard Stoloff), 1062
  Mutagenic Action of — on Transforming DNA and Inhibition of DNA Template Activity *in vitro* (Veronica M. Maher and William C. Summers), 68
Age. — of Cosmic Rays and Abundance of Antimatter in the Galaxy (L. Marshall Libby), 166
  — of Pulsar *PSR* 0833-45 (I. S. Shklovsky), 252
  Chromosome Loss compared with Chromosome Size, Age and Sex of Subjects (P. Neurath, K. DeRemer, B. Bell, L. Jarvick and T. Kato), 281
  Neurosecretion-like Material in the Hindbrain of Ageing Sheep and Sheep Affected with Natural Scrapie (A. Bignami, Elizabeth Beck and H. B. Parry), 194
Ageing. Senescent Changes in the Heart of *Drosophila repleta* Wollaston (G. E. Burch, R. S. Sohal and L. D. Fairbanks), 266
Aggression. Intensity of — in the Crayfish, *Orconectes virilis* (Hagen) (Donald B. Heckenlively), 180
Agricultural Land Services, *news*, 901
Agriculture Developments versus Population, 1
Agriculture Finance, *news*, 582
Air Pollution, *news*, 681
Air Shower. Frequency Spectrum of — Radio Pulses (H. R. Allan, R. W. Clay and J. K. Jones), 253
"Airborne Organism". — Identified (A. C. Neville), 198; (David S. Smith), 199
Airborne Particles. Deposition and Uptake by Cattle of Particles (A. C. Chamberlain), 99
Aircraft Smoke Pollution, *parliamentary news*, 680
Aircraft, VTOL, *news*, 577
Airflow Receptor. Antennae: Another Wind-sensitive Receptor in Locusts (M. Gewecke), 1263
Airport, Third London *news*, 466; (W. R. P. Bourne), *correspondence*, 773
Alcohol. Decomposition of Isopropyl — photosensitized by Zinc Oxide (Heinrich Dieter Muller and Friedrich Steinbach), 729
Alcohol in Ireland, *miscellaneous intelligence*, 991
Alcohol Dehydrogenase. Differences in E and S Chains from Isoenzymes of Liver — (Hans Jörnvall), 1133
Aldabra. Sublittoral Reef Phenomena of — (J. Barnes, D. J. Bellamy, D. J. Jones, B. A. Whitton, E. Drew and J. Lythgoe), 268
A-Levels. — and University Performance, (D. G. Bagg), 1105
Alga. Gliding in a Blue-Green —: a Possible Mechanism (Lawrence N. Halfen and Richard W. Castenholz), 1163
  Soluble Nitrogenase from Vegetative Cells of the Blue-Green — *Anabaena cylindrica* (R. V. Smith and M. C. W. Evans), 1253
Algae Conference in India, *news*, 320
Algae: "Redsnow", *news*, 587
Algae. Eustigmatophyceae — a New Algal Glass with Unique Organization of the Motile Cell (David J. Hibberd and Gordon F. Leedale), 759
Alginic Acids. Crystalline Structure of — (E. D. T. Atkins, W. Mackie and E. E. Smolko), 626
Alkali Metal Thiocyanate. Crystal Structure of a Cyclic Polyether Complex of — (D. Bright and Mary R. Truter), 176
Alkaloids. — of an *Ipomoea* Seed known as *Kaladana* in Pakistan (Charles I. Abou-Chaar), 663
Allelopathy. Root Exudation of Herbicides by Woody Plants: Allelopathic Implications (C. P. P. Reid and W. Hurtt), 291
Allergic Encephalomyelitis. Increases in Serum Lactate Dehydrogenase in Experimental — (A. E. Kaplan, L. V. Brown and J. Salk), 384
Allostery. Allosteric Interactions in $(Na^+ + K^+)$-ATPase (T. Tobin, S. P. Banerjee and A. K. Sen), 745
Allostery in Enzyme Regulation, *news*, 319
ALS Globulin. Effect of — on Amino-acid Incorporation by Human Peripheral Lymphocytes (H. Bétuel, G. B. Richard, L. Colobert and L. Revol), 549
Altitude Effects. — on the Biological Half Life of Caesium in Man (J. Rundo and C. R. Richmond), 83
α-Amanitin. Specific Action of — on Mammalian RNA Polymerase Protein (S. T. Jacob, E. M. Sajdel and H. N. Munro), 60
Ameliotes malgassicus, *news*, 224
Amines. Charge Transfer of Tropylium and *N*-Heterocyclic Cations with Aromatic — (T. G. Beaumont and K. N. C. Davis), 632
  Secondary — in Cooking (A. Courts), *correspondence*, 302
Amino-acids. Effect of ALS Globulin on — Incorporation by Human Peripheral Lymphocytes (H. Bétuel, G. B. Richard, L. Colobert and L. Revol), 549
  Effects of Lithium on — in the Mouse Brain *in vivo* (F. V. DeFeudis and J. M. R. Delgado), 749
  Piezoelectric Resonances in — (D. Vasilescu, R. Cornillon and G. Mallet), 635
L-Amino-acid Oxidase. —, a Bactericidal System (Robert C. Skarnes), 1072
Amino-acid Sequence making the Longest English Word, *miscellaneous intelligence*, 8
γ-Aminobutyric Acid. Distribution of ^{14}C-Thiosemicarbazide in the Rat Brain: an Attempt to localize Sites of — Production (Bertalan Csillik and Elizabeth Knyhar), 562
Ammonia Ice in Saturn's Rings, *news*, 687
Ammonite Evolution, *news*, 1101
Amphetamine. Effects of 6-Hydroxydopamine on CNS Catecholamines, Spontaneous Motor Activity and — induced Hyperactivity in Rats (K. D. Evetts, N. J. Uretsky, L. L. Iversen and S. D. Iversen), 961
  Investigation of *p*-Methoxyamphetamine Excretion in — Induced Psychosis (B. M. Angrist, J. W. Schweitzer, A. J. Friedhoff and S. Gershon), 651
Analysis. Absolute, Unambiguous Ultramicroanalysis of Metabolites present in Complex Biological Extracts (J. R. Majer and Alan A. Boulton), 658
Analytical Group of the Society of Analytical Chemistry, *news*, 1104
Angara Reservoirs, Geological Effects, *news*, 7
Angiotensin Converting Enzyme. Some Properties of — in the Lung *in vivo* (K. K. F. Ng and J. R. Vane), 1142
Amphibian. Stimulation of Mitosis in — Kidney by Organ Specific Antiserum (D. P. Chopra and J. D. Simnet), 657
Amphibian: Ancestry, *news*, 1101; Evolution, *news*, 904
Amsterdam Excavated, *news*, 1090
Anaesthetics. Effects of General — on Na^+ Transport in Human Red Cells (M. J. Halsey, E. B. Smith and T. E. Wood), 1151
Angiotensin I Converting Enzyme. Activity of Various Fractions of Bradykinin Potentiating Factor against — (S. H. Ferreira, L. J. Greene, V. A. Alabaster, Y. S. Bakhle and J. R. Vane), 379
Anglerfish Islets. Biosynthesis of Insulin in — (Anthony C. Trakatellis and Gerald P. Schwartz), 548
Animal Experiments, *parliamentary news*, 495
Animal Foodstuffs with Antibiotics, *news*, 311
Anisoles. Microinvasion of Epidermis caused by Substituted — (P. Grasso and Christine C. Rostron), 188
Anisotropic Media. Stoneley Waves in — (T. C. Lim and M. J. P. Musgrave), 372
Annual Production. — and Respiration in Animal Populations (S. McNeill and J. H. Lawton), 472
Anopheles annulipes. Transmission of *Plasmodium berghei* (NK 65 Strain) by *Anopheles annulipes* Walker (Elizabeth C. Kalucy and B. McMillan), 97
Antarctic and Arctic Russian Expeditions, *news*, 118
Antarctic Building Techniques, *news*, 221
Antarctic Research, US, news, 121
Antennae. —: Another Wind-sensitive Receptor in Locusts (M. Gewecke), 1263
Anthropology, *miscellaneous intelligence*, 495
Antibiotics. Discreteness of Conductance Change in Bimolecular Lipid Membranes in the Presence of Certain — (S. B. Hladky and D. A. Haydon), 451
Antibiotics Action, *news*, 901
Antibiotics in Animal Foodstuffs, *news*, 311
Antibiotics Mechanisms, *news*, 795
Antibody. Demonstration in Sarcoma Patients of Anti-tumour — which Fix Only Human Complement (F. R. Eilber and D. L. Morton), 1137
  Effect of DNA Tumour Virus on — Forming Cells in Neonatally Infected Hamsters (Herman Friedman and Herman Goldner), 455
  Fractionation of — against Staphylococcal Nuclease on 'Sepharose' Immunoadsorbents (Gilbert S. Omenn, David A. Ontjes and Christian B. Anfisen), 189
  Inhibition of Primary — Response by *E. coli* Asparaginase (Morton D. Prager and Ina Derr), 952
  Lymphocyte Cytotoxic — in Systemic Lupus Erythematosus (Kamal K. Mittal, Roger D. Rosen, John T. Sharp, Martin D. Lidsky and William T. Butler), 1255
  Properties of Protective Malaria — (S. Cohen and G. A. Butcher), 732
Antigen. Antigenic Expression of a Murine Lymphoma during Growth *in vitro* (Matko Cikes), 645
  Antigenic Site(s) of Synthetic Human Calcitonin *M* (Felix M. Dietrich and Werner Rittel), 75
  Antigenic Properties of a Homogeneous Tobacco Mosaic Virus-Hapten Conjugate (L. I. Slobin), 698
  Evidence against the Presence of H2 Histocompatibility — in Ehrlich Ascites Tumour Cells (L. Chen and J. F. Watkins), 734
  Failure to detect an — associated with Hepatitis in a Community Epidemic (James W. Mosley, Lewellys F. Barker, N. Raphael Shulman and Milford H. Hatch), 953

  - Localization of — associated with the Pollen Grain Wall by Immunofluorescence (R. B. Knox, J. Heslop-Harrison and C. Reed), 1066
  - Radioimmune Assay for — (Gabriel V. Foschi and Lionel A. Manson), 853
  - Surface Leukaemic — and Malignancy of Cells in Mice infected with Mazurenko Virus (V. E. Gurtsevich, N. P. Mazurenko, E. I. Jarova, N. A. Probatova and G. N. Stepanova), 1047
- 'Anti-helium' nuclei, *news*, 678
- Anti-lymphocyte Serum. Effect of — on the Electrophoretic Mobility of the Lymph Node Cells of the Rat (G. P. Phondyke, K. Sundaram and P. Sundaresan), 79
- **Antilymphocytic Globulin.** Effect of Adjuvants on the Immunosuppressive Properties of — (Randall A. Allardyce, Robert D. Hunter and Keith James), 1141
  - Effect of — on the Appearance of Reticular Neoplasms in SJL/J Mice (N. A. Burstein and A. C. Allison), 1139
  - Effect of Route of Administration of — on Skin Allograft Survival in Rats (R. G. Dalton, J. L. Touraine, N. F. Anderson and M. F. A. Woodruff), 1140
- Antimacrophage Serum. Transformation of Hamster Macrophages into Giant Cells with — (W. Ptak, Z. Porwit-Bobr and Z. Chlap), 655
- Antimatter. Age of Cosmic Rays and Abundance of — in the Galaxy (L. Marshall Libby), 166
- Antimicrobials. Lack of Synergy of EDTA with — in Resistant Enterobacteriaceae (Harold C. Neu and Elaine B. Winshell), 763
- Antimicrobial Substances. Absence of — in the Egg Capsules of Millipedes (Thomas Eisner, Stanley A. Zahler, James E. Carrel, Dorothy J. Brown and George W. Lones), 661
- Aphid. Suspected Insecticide Resistance Mechanism in the Peach–Potato — (V. F. Eastop and C. J. Banks), 970
- **Apollo 11.** Carbon Compounds in — Lunar Samples (Bartholomew Nagy, Ward M. Scott, Vincent Modzeleski, Lois Anne Nagy, Charles M. Drew, William S. McEwan, Joseph E. Thomas, Paul B. Hamilton and Harold C. Urey), 1028
  - Gaseous Species in Equilibrium with the — Holocrystalline Rocks during their Crystallization (T. R. Wellman), 716
- Apollo 11: Data, *news*, 15; Lunar Science Conference, *news*, 321
- Apollo 12: Moon Rocks Distribution, *news*, 782; Report, *news*, 1194
- Apple Scab Disease. Antagonism between the Effects of Kinetin and Extracellular Metabolites of the Pathogen in — (D. S. Kirkham and R. C. Hignett), 388
- Aphrodite Research by Dr Iris Love, *miscellaneous intelligence*, 120
- ARC, and Plant Breeding, *news*, 779
- Archaeology Mathematics, Conference, *news*, 1182
- Archeology Underwater and the Law, *news*, 1090
- Architecture Civic Trust Awards, *news*, 493
- Architecture School Merger Cancelled, *news*, 575
- Arctic and Antarctic Russian Expeditions, *news*, 118
- Arctic Norway Geology, *news*, 313
- Argentina. Palaeomagnetism of some Middle Jurassic Lavas from South-east — (D. A. Valencio and J. F. Vilas), 262
- Ariel Vertebrate. Flying Speed of the Largest — (Cherrie D. Bramwell and G. R. Whitfield), 660
- Artery Growth. Post-natal Growth of the Arterial Net in the Human Cerebral Pia Mater (Deowattee Harnarine-Singh and John Baskerville Hyde), 86
- Ascites Sarcoma. Effect of L-Asparaginase from *Aspergillus terreus* on — in the Rat (Lavinia Carta de-Angeli, F. Pocchiari, Serena Russi. A. Tonolo, Victoria E. Zurita, E. Ciaranfi and A. Perin), 549
- Asiatic Flu Conference, *miscellaneous intelligence*, 217
- Asparaginase. Inhibition of Primary Antibody Response by *E. coli* — (Morton D. Prager and Ina Derr), 952
- L-**Asparaginase.** Effect of — from *Aspergillus terreus* on Ascites Sarcoma in the Rat (Lavinia Carta De-Angeli, F. Pocchiari, Serena Russi, A. Tonolo, Victoria E. Zurita, E. Ciaranfi and A. Perin), 549
  - Immunosuppression by — (M. C. Berenbaum), 550
  - Inhibition of ^{3}H-Thymidine Incorporation into Rat Liver Nuclei by *E. coli* — (Siegfried Seeber and Ulrich Wesker), 652
- L-Aspartate Esters. Orientation of Polypeptide Side Chains in Solution (E. M. Bradbury, B. G. Carpenter, C. Crane-Robinson and H. Goldman), 65
- Association of Teachers in Technical Institutions, Report, *news*, 782
- Astronomers, Chinese, *miscellaneous intelligence*, 894
- Astronomer. Lockyer as — (A. J. Meadows), 230
- Astronomical Society Presidential Address, *news*, 686
- Astronomy. High Energy Gamma-ray — (G. G. Fazio), 905
- Astronomy: Galaxy Machine, *news*, 308; Society, *news*, 497
- Astronaut Death, *news*, 216
- Atlantic. Umbellulidae Distribution extended in the — (W. Jahn), 1068

ERRATA INDEX

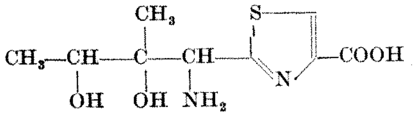
Erratum. In the article "Nucleotide Sequences Present within the 16S Ribosomal RNA of *Escherichia coli*" by P. Fellner, C. Ehresmann and J. P. Ebel (*Nature*, **225**, 26; 1970), the figure 69 on line 5, page 28, should read 59.

Erratum. In the paper "Genetics of NADP Isocitrate Dehydrogenase in *Paramecium aurelia*" (*Nature*, **225**, 181; 1970), line 16 on page 182 should read "heterozygote pattern (IDH_m 1–2) is consistent with".

Erratum. In the article "Stimulation by Cyclic AMP of Intrinsic Protein Kinase Activity in Ox Brain Membrane Preparations", by M. Weller and R. Rodnight (*Nature*, **225**, 187; 1970), the ordinate of Fig. 1 should read: nmoles [^{32}P]-phosphorylserine/mg protein.

Erratum. The author of the article "Effects of Histamine on the Toad Spinal Cord" (*Nature*, **225**, 196; 1970) is A. K. Tebēcis.

Erratum. The following corrections should be made to the article "The Structure of Thiostrepton" (*Nature*, **225**, 233; 1970): In Table 1, page 234, all minus (−) signs should be replaced by the letter L and plus (+) signs by the letter D; similar corrections should be made in Fig. 2, page 234, and on line 33 of page 235. In Table 1, the chemical formula of thiostreptine is



In ref. 7, the name of the first author is Cross, D. F. W.

Erratum. In the article "The Moon at Houston" (*Nature*, **225**, 321; 1970), the second sentence under the sub-heading Chemical Composition on page 326 should read: "Of the ninety-two elements in the periodic table, results are now available for seventy-nine".

Erratum. In the article "Activity of Various Fractions of Bradykinin Potentiating Factor against Angiotensin I Converting Enzyme" by S. H. Ferreira, L. J. Green, V. A. Alabaster, Y. S. Bakhle and J. R. Vane (*Nature*, **225**, 379; 1970), the abbreviation pGa on line 12 should read PCA (pyrrolidone carboxylic acid).

Erratum. In the article "Growing Pains in British Universities" (*Nature*, **225**, 407; 1970), the second and third sentences in the third paragraph should read: "Fig. 1 shows that between 1959 and 1965, expenditure increased at an average annual rate of about 18 per cent, while student numbers rose by about 7 per cent a year. But after 1965, when Colleges of Advanced Technology received university status, the increase in expenditure seems to have been reduced to about 9 per cent a year, while student numbers continued to rise at an average yearly rate of about 8 per cent".

Corrigendum. At a meeting of the Parkinson's Disease Society on February 11 the impression arose that patients involved in trials of L-dopa would have to stop taking the drug when trials are completed. (*Nature*, **225**, 675; 1970.) Professor J. N. Walton, chairman of the MRC working party on L-dopa, has pointed out that this is not correct, and that patients who benefit from L-dopa have been guaranteed a continuing supply after completion of trials.

Erratum. The title of the article by Jay A. Levy and Robert J. Huebner (*Nature*, **225**, 949; 1960) should read "Association of a Murine Leukaemia Virus from a Mouse Lymphoma (2731/L) associated with Reovirus Type 3 Infection".

Erratum. In the title of the article by J. Ken McDonald, Benjamin B. Zeitman and Stanley Ellis (*Nature*, **225**, 1048; 1970), the word "appropriate" should read "inappropriate".

Erratum. In the review of "A Short History of Botany in the United States" (*Nature*, **225**, 1078; 1970), the second and third sentences of the first paragraph should read: "The eleventh International Botanical Congress was held in Seattle in August 1968. This volume outlines the growth of knowledge . . ."

Erratum. In the article "New Finds at the Swartkrans Australopithecine Site" by C. K. Brain (*Nature*, **225**, 1112; 1970), a penultimate sentence should be added to the paragraph beginning "In 1958 . . . " on page 1113: "A concentration of coarse material is visible in the outer cave filling, against the N. wall, just east of the face worked by Broom and Robinson".

Erratum. In the article "The Man who Lived with Australopithecines" (*Nature*, **225**, 1188; 1970), it was implied that the stone industry recovered from the Swartkrans cave site was contemporaneous with the Oldowan culture from Bed I at Olduvai, thus making it about 1·75 million years old. The comparison should, however, have been with the much younger culture from Bed II at Olduvai.

Erratum. In the article "Bremsstrahlung Radiation in an Intense Magnetic Field and Emission from Pulsars" by Hong-Yee Chiu and Vittorio Canuto (*Nature*, **225**, 1230; 1970), equation 5 should read:

$$\alpha_\omega = \frac{8\pi^3 c^2}{n_r^2 \omega^2}\, 2m \int_0^\infty \left[f(p_z')\, \frac{\partial}{\partial p_z'} \left(\frac{Q_\omega(p_z')}{p_z' + p_z}\right) + f(-p_z')\, \frac{\partial}{\partial p_z'} \left(\frac{Q_\omega(p_z')}{p_z' - p_z}\right)\right] \mathrm{d}p_z' \qquad (5)$$

Erratum. The book *Matrix Algebra for Business and Economics* was incorrectly priced at 40*s* (*Nature*, **225**, xxxii; 1970). It costs 140*s*.

An Index of Quality

The Pye Trap Index Level Selector is a brilliant new addition to the accessories available with the Series 105 Automatic Preparative Chromatograph. In conjunction with the instrument's punch tape control system, this highly sophisticated control unit, with an electric comparator circuit, achieves an exceptional degree of accuracy in component and fraction collection – even at the end of a separation lasting several hours. Trap rotation and sample collection at any level on the chromatogram are initiated independently of the recorder by the amplifier's signal. And up to six different actuation stages are available. Programming is straightforward – you press the command buttons either to synchronise the tape with the chromatogram and index a trap, or simply to index a trap, then dial the amplifier output level at which the operation is to be carried out.

Write or 'phone for full details of the Pye Series 105 Automatic Preparative Chromatograph and its Index of Quality.

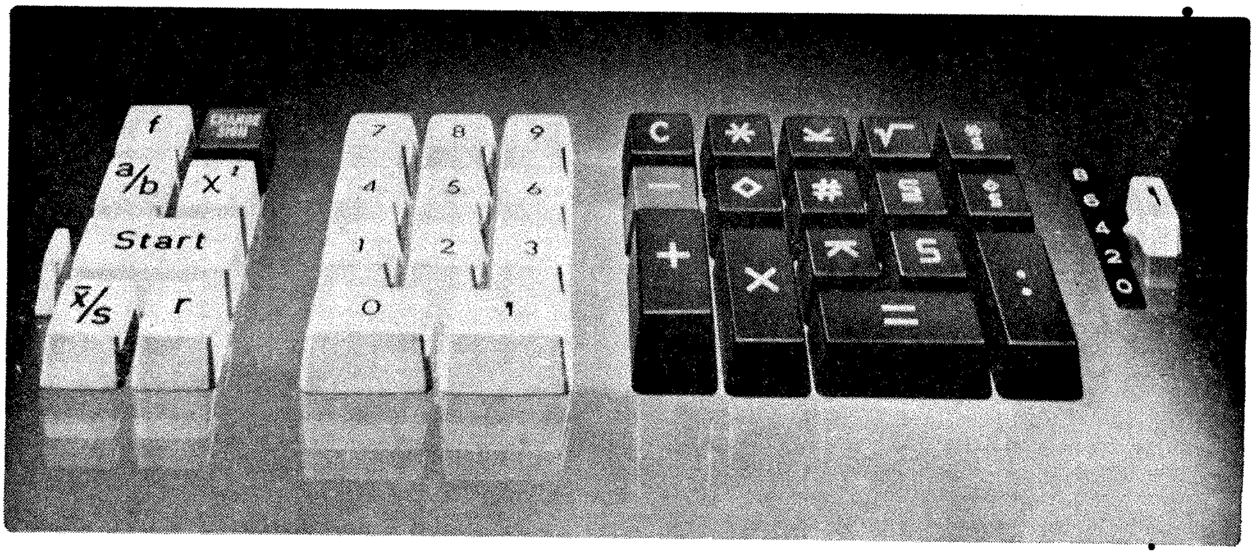
DIEHL sigmatron

Electronic Calculating System with Pre-programmed Statistical functions



DIEHL sigmatron is the first calculating system specifically designed for Statistical calculations. By pre-programmed functions, Statistical calculations are reduced to one key operations. For instance, to obtain the Arithmetic Mean and Standard Deviation enter data on the keyboard and touch the pre-programmed key. After entry of the data is completed you need only touch the same pre-programmed key to obtain the results immediately. Linear Regression, Chi Square, Coefficient of Correlation are all reduced to the simplicity of one key operation. DIEHL sigmatron also gives you a powerful and effective calculating performance with ten separate memories, automatic square root, automatic decimal selection up to 8 places and a complete check of each figure, each step and each result.
If you prefer to make your own programs, DIEHL combitron S has 10 Program/Memory registers providing a capacity of 120 steps with branching and looping.
For external input of data, DIEHL dilector – punched tape reader – is available.

NATURE Volume 225 JANUARY 31, 1970

The Prophets of Pollution

If anyone doubted that pollution has now usurped the place of original sin in the public consciousness, he has only to read the diatribes of one of the more colourful of contemporary prophets, Professor Ernest Sternglass. Like Moses calling down the death of the Egyptian firstborn, Professor Sternglass is convinced beyond all reasonable doubt that the fall-out from nuclear testing has caused the death of sometimes 400,000 and sometimes two million children in the United States. A prophet, however, is not honoured in his own country, and this week Professor Sternglass was in London to attend the screening of a film on pollution made by Thames television and entitled, with suitable Old Testament flavour, "And on the Eighth Day".

Professor Sternglass is not the run of the mill kind of prophet. He has been vice-president of research at the Westinghouse Research Laboratory for 15 years and is now professor of radiation physics at the University of Pittsburgh. He is a forceful speaker, both in public and private, especially when a gust of indignation lends a gleam to his eye that would outface Savonarola. That he is sincere in what he believes goes without saying, and if he deliberately courts publicity it is not for delight of being in the public eye but because he considers his views have not received a fair hearing.

The difficulty of getting a fair hearing seems to be an important plank of Professor Sternglass's platform. This week he was complaining that *Nature* had refused to publish both the original statement of his case and a reply to the critique by Professor J. Rotblat and Dr Patricia L. Lindop (*Nature*, **224**, 1257; 1969). He also affirmed that Professor Rotblat had neglected the courtesy of sending a copy of his critique to him before publication.

Among the documents on public display were xerox copies of a letter from Dr H. J. Dunstan, secretary of the forthcoming International Radiation Protection Association Congress, saying that "the pressure of papers submitted" has made it impossible to accept an abstract of one of Professor Sternglass's articles. Dr Dunstan adds his hope "that it will still be possible for you to attend the Congress and participate in the discussions". At the same time Professor Sternglass is eager to demonstrate the acceptance of his views by the scientific community, and he also produced a letter from Professor John T. Edsall of Harvard University saying that, if Professor Sternglass could take care of certain minor points in a manuscript, "I would be glad to send a letter to Philip Abelson [editor of *Science*] urging him to publish your article so that the evidence you have to present could be brought out into the open for all interested persons to debate".

Is there really a conspiracy against Professor Sternglass and all his works? The young film producers at Thames television, which sponsored Professor Sternglass's appearance, believe that there is and even dropped hints that, were it not for the refusal of *Nature* to publish Sternglass's articles, his visit to London might not have been necessary. It certainly seems that Professor Sternglass has decided to appeal to the public over the heads of his scientific colleagues in the belief, perhaps, that if you can't join them you can beat them. Professor Sternglass does not himself claim that there is a conspiracy against him, but in allowing others to so believe he is paying possibly too little heed to the ways and means of scientific communication.

The truth is that the truth is hard to find. It does not lie on plates or hang from trees. This is why over the years various conventions and by-laws have been formulated whereby to keep the congested channels of scientific communication reasonably free from spurious traffic. Once a false result gains a place in that sacred corpus known as "the literature", it can on occasions do untold harm and waste innumerable hours of valuable time. It is hardly surprising that editors of scientific journals try to exclude articles which fall in this category, particularly when they carry the implications of Professor Sternglass's hypothesis. That is a long way from conspiracy, and the fact that more than one editor has rejected Professor Sternglass's papers whether on these or other grounds could be a sign of the looseness of Professor Sternglass's arguments rather than of the tightness of the conspiracy. Professor Sternglass's original paper was rejected by *Nature* because of its inherent deficiencies. Far from not being shown to Professor Sternglass before publication, the critique by Lindop and Rotblat was held up

Nature in North America

From the beginning of next week, *Nature* will maintain an office in Washington DC. for several weeks to allow him the chance of replying. The reply was rejected because it restated the original case instead of answering the criticisms. None of this implies that Professor Sternglass is wrong in what he has to say. He may indeed be right. But he has not yet argued his case in a scientifically acceptable style. In other words, there is a substantial possibility that he is entirely wrong.

To publish a hypothesis in this state of uncertainty is to risk the usual confusion created by a false result together with the dangers of crying wolf too often. In the present climate of concern about pollution it is all too easy to misinform the gullible and add fuel to the sense of hysteria in which, for example, the Minister of Agriculture recently banned cyclamates and Lady Summerskill called in the House of Lords for a complete withdrawal of all contraceptive pills. People such as Professor Sternglass should perhaps ask themselves exactly what cause they are serving when they simplify a complex issue and present it in emotive terms. To say, for example, as Professor Sternglass does in the Thames television programme on pollution, that "something like 100,000 children in Britain" have died because of nuclear testing is the statement of a propagandist, not of a scientist. Professor Sternglass doubtless knows when he is playing one part and when the other, but other people will inevitably be confused.

The upshot of this confusion is vividly illustrated in the television programme that brought Professor Sternglass to London. "Report on Pollution—And on the Eighth Day" is not so much a report as a wholly uncritical exposition of what various scientists interested in pollution problems have to say. The film, in consequence, is no better than its raw material, which means that when Dr Kenneth Mellanby is being interviewed it is excellent and when Professor Sternglass's views on infant mortality are followed by the triple cliché of a baby in a cot, a pregnant woman and falling rain, all to the sound of a song hinting at radioactive contamination, the result is a complete abnegation of the principles of balanced reporting.

Those who feel that a little overstatement here and there will do the cause of protecting the environment no harm should consider carefully some of the confusion that too much propaganda creates, both in the minds of television producers and in those of their audience. Like the primitive who blames the weapon instead of the murderer, the Thames television film seems to be arguing that the environment is polluted not because society has failed to control technology, but because technology exists. "However ingenious our technology, the natural laws will exact their price no matter how we try to postpone or circumvent them" is a statement marvellously redolent with ancient anti-Promethean undertones.

Must man really be forbidden to use fire? Is technology an affront to the natural order that will attract the retribution of gods? Quaint as this view may be, the harking after the ideals of the noble savage is all too easily turned into an attack on rationalism and the pursuit of scientific knowledge. Indeed, the Thames television film explicitly questions the scientific method: "The scientist, learned in one thing, may be ignorant of all else. . . . With the population exploding, knowledge scarce, the scientific method inappropriate, it is little wonder we are in this environmental mess." It is little wonder that if people of the undoubted ability and conviction of Professor Sternglass go around in girt-up loincloths prophesying fire and brimstone in advance of the basic facts being agreed upon, some of the bystanders will think men of science strange and dangerous.

Academics in Limbo

Where will it all end? As the months go by, the sense in the British universities that serious trouble can be only just around the corner begins to give way to the more awesome prospect that radical changes may take place without being recognized as such. The latest annual survey of the University Grants Committee, which is a useful document not merely for its liberality with factual information, is unfortunately unlikely to help keep people on their toes. Statistically (see page 409), there is every reason to believe that the financial squeeze of the past few years has begun to take effect. The staff–student ratio, for example, has begun to decline—not before time, perhaps. Qualitatively, the University Grants Committee has made a beginning, however slow, on the painful task of providing a better coordination for the activities of British universities, and in the process it is inevitable that some institutions will feel that their freedom is being restricted. The trouble, of course, is that there are plainly too many universities all trying to do the same kinds of things, so that the avoidance of duplication is a serious problem. But the most serious sign to show in the UGC's courtly document is the uncertainty which it discloses about the future scale of growth. Will the British Government remain committed, in the 1970s, to the Robbins doctrine that all suitably qualified people should be provided with a university place (which begs the question of what is meant by suitably qualified)? Or will there instead be a tendency to look for cheaper solutions? Much, no doubt, will depend on how the universities respond to the request made of the universities last September to consider new ways of organization. Collectively, however, the universities have less freedom of manoeuvre than they are inclined to think.

So might it not be simpler, as it would certainly be more courageous, to begin by tackling the more serious issues which overhang the British system of higher education? The lack of any mention of these important matters is the gravest defect of the UGC's new document. What, for example, is to be the relationship between the universities and the polytechnics on which, three years ago, the government falsely pinned a good deal of its hope? Will these institutions be encouraged (as they should be so long as they remain autonomous) to become so good that they resemble universities, will there instead be a foolish attempt to make them second-class institutions, or will the government (or its successor) confess the error of its ways and find some way of linking the two systems (with colleges of education included) into an integrated whole? Then what is to happen to the relationship between universities and the government? Will utter financial dependence continue to be the almost universal rule? The benefits of a broadening of the financial base consist not of mythical academic freedom but a built-in tendency towards the kind of academic diversity which is at present missing. Then there are questions of the financial relationship between universities and their students on the one hand and their teachers on the other. Is it right that British students should be financially dependent either on the local government or their parents? Is there not some halfway house in which the direct cost of university education would not be simply related to the size of its output? And is it not time that the present rigid scales of pay for academics were softened by more than the tiny percentage which has survived from the recommendation of the Prices and Incomes Board that four per cent of the salary bill should be spent on special awards to hard-working teachers? To say that the neglect of these matters for the proper coordination of postgraduate courses is to fiddle while Rome burns would be to exaggerate—but not by very much.

100 Years Ago

BOSTON

Society of Natural History, November 17.—The president in the chair. Prof. N. S. Shaler read a note on the occurrence of the remains of *Tarandus rangijer* Gray, at Big Bone Lick, in Kentucky. At a previous meeting was presented the evidence in support of the conclusion that one of the large mammals of North America, the buffalo, had recently changed its limits, and had only ranged in the Ohio valley within the past few centuries. The same locality supplies us with evidence that the caribou existed in abundance in this river basin at a time anterior to the coming of the buffalo, and probably not very long after the disappearance of the *Elephas primigenius*. Since the coming of civilised man into America, the caribou has been confined to a narrow area in the north-east part of the continent; it is questionable whether it has ever ranged during this time south of the southern limit of the State of Maine. The position in which these remains were found leaves the precise relationship in time of this species to the mammoths and mastodons a little questionable. There is, however, little doubt in my mind that, if not in existence during the later part of the time of these pachyderms, it came immediately after them. Its bones are always found below the line of the buffalo and the Virginia deer. The remains of this latter species are found only among the most recent deposits of the swamp. The disappearance from this region of this eminently boreal animal immediately after the passing away of the ancient elephants from the Mississippi valley, goes to confirm the conclusion that the climatic change which closed the period of the mammoths was from cold to warmth, and not an alteration of the opposite character.

From Nature, 1, 369, *February 3, 1870. Shaler was professor of palaeontology at Harvard.*

RESEARCH ASSOCIATIONS

Strength in Unison

THE industrial research associations, long since accustomed to life on the edges of public munificence, seem to have embarked on a strategy that will allow them at least to complain about their lot more effectively. Earlier this week, the associations collaborated to form what is known as the Conference of Industrial Research Associations, evidently intended to serve as a more effective voice than the Committee of Directors of Research Associations has been able to be—in some eyes, at least, directors are lowly fellows because they are formally the employees of the autonomous councils which are formally the fountain-heads of policy. The director of the new body is the Earl of Shannon, and it is intended that there shall be a deliberate attempt to provide a solid base from which the case for the research associations can be advanced.

There seems no doubt that the publication of the Ministry of Technology Green Paper on the reorganization of civilian research within the government has fired the zeal of the research associations, which are almost conspicuously left untouched by the proposals for reorganization. For the past few years, the central government's contribution to the finances of the research associations has been fixed at £4 million a year, which works out at about a quarter of the total budget, the remainder of which is supplied by industrial contributions. Although this kind of treatment is familiar enough among the pensioners of governments who have fallen out of favour, it seems to be felt among the research associations that the Ministry of Technology has an influence over policy which is incommensurately great compared with its financial contribution. It will be interesting to see whether the new arrangements will tempt the research associations to make a dash for freedom and do without a subvention. It may be easier to tell which way the wind is blowing on February 11, when the Conference of Industrial Research Associations plans to hold a public meeting at which Dr E. A. Davies, Joint Parliamentary Secretary at the Ministry of Technology, will be one of the speakers.

TEACHER TRAINING

Comprehensive Degrees?

by our Education Correspondent

TEACHERS have very little opportunity to help formulate policy on teacher training. This claim was made by representatives of the National Union of Teachers when they met the Select Committee on Education and Science on January 27. The NUT does, however, have strong views about the way that teacher training should be run, and submitted these to the Select Committee in a detailed document setting out a number of radical proposals. Like the National Union of Students and the Association of University Teachers, the NUT wants to see an end to the binary system. The proposals call for a major restructuring of the whole sphere of higher education, the final result being a "comprehensive university". Colleges of education should be grouped together into schools of education, attached to a university, and the NUT argues that all education students should take a four year course leading eventually to a degree.

The NUT suggests that responsibility for financing all spheres of higher education should be vested in one body, on the lines suggested by the Select Committee itself in its report on student relations. Such a system would remove the present colleges of education from the financial control of the local authorities. If they were grouped together into schools of education and brought under the control of individual universities, the NUT argues that this would "avoid wasteful duplication of courses", and would facilitate coordination of entrance requirements for higher education to "relieve the pressures which result in unnecessary specialization in secondary schools".

As far as course content is concerned, the NUT argues that there should be no dichotomy between academic and professional matters. What matters is the nature of the knowledge acquired and the understanding of how to communicate this knowledge to different age groups. Placing the schools of education in a comprehensive university would give potential teachers the opportunity to mix with students from other disciplines and this would help them to gain maximum benefit from their education. But the NUT suggests that the best way to provide links between the academic and professional aspects of training would be to appoint teacher–tutors. These would be teachers on the staff of schools where teaching practice is carried out, who would be responsible for a few students, and would work closely with college tutors.

The NUT believes that the present three year courses are too short and that they should be lengthened to four years. The NUT also suggests that the "general recognition of the need for a four year course would be a major step towards the union's ultimate goal of an all-graduate profession". The union also suggests that schools of education could provide one year courses of education for students who are unable or do not wish to take a degree course in education. Such courses are at present virtually a monopoly of the universities.

DRAGON

Now We are Ten

An opportune moment has been chosen for the publication of the tenth annual report of the Dragon high temperature reactor project, released last week, but the future probably bodes less well for the steam generating heavy water reactor which the UKAEA has on its books. Dragon is just across the way from the SGHWR at Winfrith, but the Dragon reactor is a joint effort of twelve European states and run by the European Nuclear Energy Agency. The point about Dragon is that the metal fuel cans have been done away with so that much higher temperatures can be allowed in the core—up to 1,500° C. One of the by-products of the project has been a boom in the technology of graphite which is used for the structure of the core and moderator. The high temperatures mean a high conversion efficiency in a compact reactor. Cooling is by helium gas, and one possibility which people have been talking about for this type of reactor is to use the helium to drive the turbines directly, thus cutting out the mandatory intermediate steam cycle with a further gain in efficiency.

Since the encouraging remarks about high temperature reactors made by Sir Stanley Brown at a conference in Zurich last year, the outlook has been bright for projects such as Dragon. Prototype reactors working on similar principles are in operation in Germany and the United States. Sir Stanley is chairman of the Central Electricity Generating Board, and he said that high temperature systems show an advantage of about £10 per kW over the advanced gas-cooled reactors (AGRs) such as are being built for the board at present. The point seems to have been taken by the participants in Dragon, who recently agreed to extend the project for a further three years to March 31, 1973, within a total budget for the period of £38 million.

The view of the CEGB is that an enquiry for a 1,300 MW HTR station with two reactors is likely to be issued toward the end of 1970, with the first reactor intended to come into service in 1976. But there is not going to be a rapid transfer to HTR systems and the board is probably going to continue with AGR stations to the end of the decade. Instead, the first HTR will be what is being called a "leader" station, and its performance will be watched carefully before the board goes further. The way the 20 MW Dragon project has gone seems to have persuaded the board that there is no need for a bigger prototype reactor before the leader station.

One of the charms of HTR systems as far as the CEGB is concerned seems to be that they are likely to be better than AGRs at coping with the large daily fluctuations in demand which are a feature of the British power scene. Meanwhile, with Winfrith's Dragon in a happy state, negotiations are still going on with Greece to barter an SGHWR for a consignment of tobacco.

CB WEAPONS

More Shocks from WHO

The latest contribution of the World Health Organization to the debate about chemical and biological weapons is the most alarming so far (*Health Aspects of Chemical and Biological Weapons*, WHO agencies, £1·20). Together with a catalogue of the properties of some hitherto obscure agents, the document contains a detailed calculation of the potential effects of chemical and biological agents directed at hypothetical targets—mostly densely populated cities. The document is a by-product of the work of the eighteen member advisory committee which drafted the WHO advice to the United States, later embodied in the UN report on the subject published last year.

One of the most vivid of the examples of the effects of chemical and biological weapons assumes that the agent would be the bacterium responsible for tularaemia. Although human beings do not often come into contact with the insect vectors of the disease, it is known that as few as twenty-five bacterial cells can cause infection. The report points out that even the susceptibility of the bacterium to antibiotics such as streptomycin need not prevent its use as an incapacitating agent, but that a death rate of about 25 per cent among infected people would otherwise be expected. The bacteria are easily grown, infection is easy by several routes, immunization in advance is unlikely to be effective and one consequence of the use of such an agent would probably be the establishment of pools of infection among wild mammals.

An attack with tularaemia bacteria on a city of five million people would, the report estimates, produce 250,000 infected cases and probably many more. Although most of those affected would be treated by antibiotics within 48 hours, something like 25,000 people would need to go to hospital and something like 2,500 people would die. The greatest casualties, however, would be among those escaping treatment early on, possibly by fleeing the city—the committee estimates that between 7 and 10 per cent, or possibly 2,000 people, would die, making a total death roll of 4,500 spread over 10 days. Given that a modern city with a population of 5 million is likely to include 10,000 doctors and 60,000 nurses, the report concludes that it would probably be possible for existing medical staffs to handle the consequences of the attack, at least so long as panic and severe disorganization could be avoided. This case study shows how much more resistant to an attack would be a well provided city than a city of the same size in a developing country—there, the calculation goes, 30,000 deaths within ten days would be expected.

The use of plague as an infecting agent could be expected to be more damaging. It is estimated that in a city of five million people, there would probably be 150,000 cases infected with pneumonic plague and up to 100,000 hospital cases of whom 36,000 would die. One of the most serious causes of death would be secondary infection, responsible for, say, 100,000 deaths. The report says that "burial facilities would be taxed and some difficulties could be expected". In cities of the same size without medical services for providing those initially infected with antibiotics and without hospitals on a modern scale, it is estimated that 250,000 people would die in the first and succeeding waves of infection.

Nerve gases could be as damaging as pneumonic plague, but faster. The WHO report estimates that if 150,000 people were exposed to a lethal concentration of the persistent nerve gas VX, 80,000 of them would die before help arrived and that a further 40,000 would die before help could be effective. One of the particular hazards of VX is that its persistence would play havoc with the helpers. The fact that most of the deaths would be concentrated in the first two days would only aggravate the strain on the hospitals and medical facilities.

The panel responsible for the WHO report has also calculated the likely consequences of attempts to infect public drinking water systems with various organisms. One kilogram of freeze-dried typhoid, containing more than 10^{14} organisms, is assumed to lose all but five per cent of its infectiveness on being introduced into the public water system of a city. In a modern city, something like 35,000 people would receive a sufficiently high dose to be assured of developing typhoid, and 200 or so of these would die. In less advanced cities, the same amount of freeze-dried bacillus could cause 130,000 cases and 4,500 deaths. The use of type A botulin toxin is likely to yield less certain consequences—because the first effects are likely to appear within 6 to 8 hours of ingestion, much will depend on how quickly public authorities recognize what has happened. It would be responsible, however, to conclude that 0·24 kg of toxin could cause 30,000 deaths, allowing a six-fold safety factor to account for unequal distribution.

SOLAR PHYSICS

Plans for More Facilities

A SENSIBLE plan for the development of ground-based observations of solar–terrestrial phenomena has now been published by a panel of the National Research Council in Washington (*Physics of the Earth in Space—The Role of Ground-Based Research*, available from the National Academy of Sciences). The Space Sciences Board of the NRC published in 1968 an analysis of the ways in which rockets and satellites could advance the cause of solar–terrestrial physics, but the new report, produced under the guidance of Dr Herbert Friedman, is almost lyrical in its description of what remains to be done by deploying more effective equipment on the ground.

Most of the recommendations in the new report are concerned with conventional equipment. The committee is, however, strong in its advocacy of direct observation of the Sun at radar wavelengths, and asks for the development of a scanning radiometer operating in the mid-centimetre range which would be able to resolve to within a minute of arc or better and which would produce what would be television pictures (at radio wavelengths) at the rate of one a minute. The object of this instrument would be to make possible direct observations of those regions in the chromosphere of the Sun which lie at the base of solar flares or which surround them. The panel says that the most direct attack on the problem of solar flares could be mounted by means of simultaneous X-ray mapping of the Sun from satellites and ground-based observations at radio wavelengths of features no more than a second of arc across, but the committee asks at this stage only for the study of the radio-interferometers which could help in the design of such an expensive piece of equipment. In the same way, the panel would like to see an improvement of facilities for the optical observation of the Sun, especially at places where continuous observation is possible, and it is even more enthusiastic about the need for a new instrument for the spectroscopic mapping of the magnetic field on the surface of the Sun. Less hopefully, the panel asks for money for the exchange of information from solar observations and for the exchange of people, graduate students as well as independent investigators.

The panel is downcast at the way in which financial support for cosmic ray research is declining, and asks that this tendency should be reversed, with the Environmental Science Services Administration paying hard cash for some of the uses which it makes of cosmic ray data. The National Center for Atmospheric Research has advocated work on the development of cosmic ray balloons of great endurance capable of flying at more than 120,000 feet—there is apparently great promise in a scheme for launching balloons which use liquid hydrogen as ballast—controlled evaporation could turn ballast into lift. Flights lasting several days over the polar caps (and especially in the Antarctic, where national boundaries create no problem) come high on the list, as does the need for developing instruments for balloon flights which can yield information about the momentum, charge and directional distribution of cosmic ray particles which is comparable with that obtained from ground-based equipment. For the rest, where cosmic ray studies are concerned, the panel would like to see an all-round development of present work.

Throughout the panel's report, there is a constant repetition of the need for mobile facilities for the measurement of cosmic ray neutron flux, the measurement of geomagnetic disturbances and the recording of some kinds of solar phenomena. It seems to be acknowledged that the handling of geomagnetic data is a special problem, and the panel suggests that a world-wide communication link based on a COMSAT circuit would be sensible (but there is no estimate of cost). There is, the report says, a great need for the development of programmes which will continuously monitor whistler signals received at very low frequency.

The panel has several expensive proposals for the better study of the ionosphere, the chief of which is the building in the northern United States (at the edge of the magnetic shell $L=4$) of a transmitter–receiver capable of exploiting incoherent scatter techniques in the study of the motion of plasma in the ionosphere. The cost of this proposal is said to be potentially comparable with that of the Arecibo station in Puerto Rico. The panel also asks that there should be a smaller station in the auroral zone, and suggests that this might be established by moving the incoherent scatter equipment now at Palo Alto to College, Alaska. The panel is clearly anxious that the stations at Jicamarca (Peru), Millstone and Arecibo will be kept on tight budgets, especially now that the last of the three is due to be moved from the Advanced Research Projects Agency to the National Science Foundation. The financial position of these three stations seems also to concern those who would make simultaneous optical and radio measurements of the atmosphere from stations on the ground, but the panel also urges that there should be more detailed laboratory studies of important processes in aeronomy.

To the extent that the panel's report will help agencies such as the National Science Foundation to work out a strategy for solar–terrestrial physics, the report will be valuable. Inevitably, however, it is bound to seem like wishful thinking or even special pleading so long as it lacks a detailed costing. This deficiency is no doubt one of the inevitable features of reports prepared in the splendid isolation of Aspen, Colorado.

GEOLOGY

Applied Mapping

WITH an eye on the practical applications of its services, the Institute of Geological Sciences has been putting its surveying and mapping work to good use despite difficulties in recruiting staff and in re-siting numerous offices. One economically important project mentioned in the institute's recently published annual report on 1968 (HMSO, £1·2; 1969) is a comprehensive survey of the Humberside area with a view to the optimum development of its industries, services and amenities. The field unit is revising the six-inch mapping of the area, a new marine geophysics unit has made its first ship-borne survey in the estuary and the hydrogeological department is studying the underground resources of the entire Humber drainage basin.

The engineering geology unit has played its part with a geotechnical study of the area of the new town of Milton Keynes, and maps and tables showing the variation of physical properties over the area will be ready within the next few months. This seems to have been helpful in planning the drainage for the town although too late to influence any of the major planning decisions. The institute is, however, involved right from the earliest stages of planning with all road projects costing more than a million pounds, by agreement with the Ministry of Transport.

In its programme for shallow geological mapping of the sea bed of the continental shelf, the institute hopes to encourage commercial firms to carry out more detailed deep surveys in areas which seem likely to have mineral deposits. The institute publishes these maps in a new IGS report series, and it has so far surveyed the North Irish Sea, the sea of the Hebrides and Minch, the Clyde and the Firth of Forth. One deep reflexion seismic survey was commissioned in Cardigan Bay, a deep sedimentary basin of potential interest to oil companies.

The radiogeological department, under a £250,000 contract from the United Kingdom Atomic Energy Authority, is examining two areas in North Scotland and the Midlands for uranium deposits. The results have not yet been fully analysed, but at least four areas have been identified where the radioactivity can be attributed to uranium and one where there is thorium. Hydrogeochemical reconnaissance seems to be an effective prospecting technique in this environment. A new twelve-inch mass spectrometer in the isotope geology unit is being used mainly for geochronological work using K-Ar, Rb-Sr and U-Pb dating techniques. An interesting development has been work on stable isotope ratios. The institute hopes, for instance, to set up a new unit to study the relationship between O^{16}/O^{18} ratios and the temperatures of formation of rocks and mineral deposits and is also interested in examining sulphur and hydrogen isotopes which may give information about the fluid inclusions in rocks and minerals.

LINNEAN SOCIETY

Successful Appeal

by our Botany Correspondent

FIFTEEN months after it was launched, the appeal for development of the rooms of the Linnean Society in London has drawn gifts and promises of more, totalling £69,000. So successful has it been that the first phase of alterations at Burlington House is already under way. The new strongroom is complete and only has to dry out before the collections of plants, shells, insects and fishes, made by Linnaeus in the eighteenth century, can be moved in from the wooden cabinets they have occupied since the society moved into its rooms in 1857.

The latest piece of good news for the organizers of the appeal came just before Christmas when they heard that the Swedish Government had approved a grant of 100,000 Swedish crowns (about £8,000) towards the provision of suitable premises for the collections. Linnaeus was of course a Swede, and the impetus for the gift seems to have come from the Royal Swedish Academy of Sciences at the instigation of Professor S. O. Horstadius, a foreign member of the Linnean Society. Other gifts from Sweden have come from HM the King, the University of Uppsala and the Swedish Match Co., as well as the Academy of Sciences.

The most generous single British donations have come from the Royal Society (£4,970) and from the Drapers Company (£5,000) towards the cost of a new council room as a memorial to the late Sir Frederick Stern, former master of the company and treasurer of the society. In its report on the appeal the society notes that the response of industry and commerce has been reasonable in view of the present financial climate and the rather specialized nature of the appeal. BP and ICI were the most generous donors, giving £1,000 and £500 respectively. Many scientific societies have also contributed, and the Linnean Society hopes that some of them will be able to make use of the modernized rooms for their meetings.

The work already completed or under way in the basement, which as well as the strongroom includes the provision of new cloakrooms and heating and ventilation systems, will cost about £42,000. Further plans have been drawn up for improvements to the library and lecture room and the provision of a council room and offices. This work, due to begin soon, will cost more than £30,000, and so the appeal is by no means closed. If sufficient funds are available there are a few more improvements, particularly to the library, which the society would like to see effected.

The library of the Linnean Society has considerable historical interest, because it is founded on the libraries of Linnaeus himself and J. E. Smith, the wealthy friend of Sir Joseph Banks, who bought the collections and books for £1,088 5*s* from Linnaeus's family in 1783. The Linnean Society was formed five years later, meeting at the Marlborough Coffee House in London, with Smith as one of the seven founder members. After Smith's death in 1828 the society bought the collections and books from his executors, and has had them ever since.

CARNEGIE OBSERVATORIES

Rechristening Mount Wilson

THE Mount Wilson and Palomar Observatories in California are in future to be known jointly as the Hale Observatories. This was announced recently by the Carnegie Institution of Washington and the California Institute of Technology. The immediate benefit of the change will be that innocents will not in future fall into the trap of calling Palomar Mountain Mount Palomar, but it is also intended that there should be a new method of planning work at the observatories, which will separately be known by their old and separate names. The director of the observatories will remain Dr Horace W. Babcock, but the new arrangements specify that there should always be a director from one of the observatories and an associate director from the other. In fact, Dr J. Beverly Oke has been appointed associate director of the Hale Observatories. The allotment of observing time will be entrusted to an observatory committee of eight people.

The permanent staff of the observatories is now more than 120 strong and includes nineteen astronomers, many of whom are also members of the faculty at the California Institute of Technology. The naming of the observatories after George Ellery Hale is of course appropriate—Hale founded not merely the Mount Wilson and Palomar Observatories but also those at Kenwood and Yerkes. Although experienced people say that seeing conditions at Mount Wilson have never been as good as in the years during the war when Los Angeles was blacked out, the two observatories remain remarkably usable. The 200-inch Hale telescope on Palomar Mountain, for example, had 238 complete nights of seeing in 1968 and 62 nights when it could be used for part of the time.

LONDON

Preventing a Flood

by our Planning Correspondent

WHILE the British Government has not yet firmly committed itself to the form or the location of a barrage or barrier across the River Thames as a defence against a tidal flood, it has agreed that London and Lower Thames-side must be protected in some form, although it does not regard the likelihood of a serious flood with quite the same alarm as does the Greater London Council. Nevertheless, the Minister of Housing and Local Government, Mr Greenwood, did say in a written parliamentary answer on January 20 that no time should be lost in completing the further studies called for in a report on various defence systems which the GLC has just submitted to the minister, and that the government and the responsible authorities "will then decide as a matter of urgency on the nature and siting of the defences required".

The GLC report to which the minister referred contains the council's preliminary conclusions from a detailed study into what it believes to be the growing threat of a flood caused by a combination of circumstances—the sinking of the south-east at the rate of about a foot a century; the increasing height of the tides in the Thames (about 3 feet a century at London Bridge) compared with the general sea level; the reclamation of low lying land alongside the river over the centuries which has stopped the build-up of silt; and the channelling of the river through the building of flood walls which has raised the general level of water. A high spring tide, a "surge" of moving water from the North Atlantic, an adverse wind, heavy rainfall and drainage off the land could, in the council's opinion, cause a disastrous flood.

The council has worked on the basis of providing protection against a high water level six feet above the levels reached by the Thames in the floods of 1953, taking into account the sinking of the land, the increase in tidal range and so on. This new high water level, the council says, would put the risk of flooding at about 1 in 10,000 in 1980, about 1 in 6,000 in 2010 and about 1 in 4,000 in 2030. At present, 55 square miles of London, with a population of 1,200,000 people, are below this new level. Walls an extra six feet high along the river banks would, however, be unacceptable from the amenity point of view in most parts of London. The council has therefore looked into other ways of dealing with the problem and, since 1968, has spent £250,000 (half of which is being paid for by the government) on investigations which have included the commissioning of a 400-foot concrete model of the Thames at the Hydraulics Research Station (see *Nature*, **221**, 507; 1969), computer predictions of surge tides which might be expected in the future, measurements of silting and water movement in the river, and other field studies. Of all the various types and locations of a fixed barrage or a movable barrier which could be used in conjunction with a raising of the riparian walls in places, the council favours a tide-control barrier in the Woolwich/Limehouse area just upstream of the Royal Docks; or failing this, a similar barrier in the Crayfordness area farther downstream. The barrier in either site would operate by closing at times of great risk between September and March at a point during the ebb tide, reopening on the following flood tide unless there was a warning of a surge, when it would remain shut. It would be provided with a lock so that medium-sized ships could pass through. It is estimated that the Woolwich barrier would take about 7 years to build at a cost of about £50 million; at Crayfordness, the barrier would take about 11 years to build and would cost about £60 million.

While the GLC's suggestions for flood protection have been generally welcomed, there are fears about the extra cost to shipping if the barriers are built—reckoned to be £250,000 a year in the case of a Woolwich barrier, and £1 million through shipping delays if the Crayfordness barrier is built—and that the barrier if built at Woolwich would be an eyesore. Presumably, these economic and environmental matters will be sorted out in the next stage of the GLC's investigations.

ARCHAEOLOGY

Cargo of Mortars

It is original of the Gollcher Foundation administered by the National Museum of Malta to choose as the subject of the first publication in its archaeological monograph series an underwater wreck site. Captain Olof Gollcher, a Swedish nobleman and Knight of St John who died in 1962, left his home in Malta and its contents as a national collection and established a fund in support of archaeological studies. He was an enthusiast of underwater archaeology, so it is appropriate in several ways that the first volume of the Gollcher series deals with a wreck off Malta studied by Miss Honor Frost, who has won her international reputation in this exacting science through work in the Mediterranean. *The Mortar Wreck in Mellieha Bay*, just out from the Appleton Press (EC1) (38 pp., 25*s*), deals with a second century Roman wreck. The ship was apparently bound from southern Italy to North Africa when it was blown by a *gregale* (north-easterly wind) on to "rocks awash", as they are currently labelled on the marine chart, in the middle of the bay.

The prime cargo consisted, rather improbably, of mortars of various sizes but distinctive manufacture. Into the paste was mixed, before firing, sizable grits to give "bite" in the pounding up of pulses and grains. The grit material has been identified as *andularia*, a type of feldspar of very limited distribution in Europe. Piedmont appears the most likely source in this case. That Roman merchants had an export trade of mortaria to the colonies is surprising. But they have been found on land in places as far apart as Syria, Jerusalem, Strasbourg and even Newcastle. Some of the Mellieha wreck mortars are 1·3 metres across. The cargo also included glass, the dating and analysis of which have proved a valuable contribution to the history of glass technology.

Miss Frost observes that the scholarly value of wreck sites is still scarcely appreciated, largely because of slow and inadequate publication. Wrecks, being "closed groups", are important both for dating and for deducing the provenance of antiquities. When their controlled excavation becomes the rule, they should be such a reliable source of information that archaeologists debating attributions may one day ask: "Is such and such a view confirmed by findings from *wreck* excavation?" At least Miss Frost cannot be faulted on publication.

INDUSTRIAL RESEARCH

Keep Technology Pure

The translation of ideas from pure research into technology must occur in a research environment, according to Dr A. P. Speiser, the director of research of Brown, Boveri and Company, speaking at the Institution of Electrical Engineers in London recently. He explained how Brown, Boveri, which is an international concern, has been applying this concept in the design of its new research centre in Switzerland, and why it is vital to get the right balance and coupling between the pure and applied aspects of a company's research effort.

Dr Speiser was quite critical of some of the methods used to select research projects in industry. A common pitfall, he said, was to justify the lack of scientific content in a piece of research by its possible practical benefit, and to justify the lack of the latter by possible scientific benefit. He thought that some work on controlled nuclear fusion fell into this category. An important criterion for evaluating the worth of a project should be the standing of the group involved, he said, and it is also a good test if the research workers are well respected in university circles.

A sound test of the value of a technological project is whether it fits in somehow with the overall strategy of a company, Dr Speiser said. Close personal contacts between research and production departments are vital for this, but he was still convinced that the majority of technologists in a firm should work within the research laboratories.

Brown, Boveri has an annual turnover of about £400 million, most of which comes from Switzerland, West Germany and France. Dr Speiser pointed out that it had been the aim of his company to concentrate its whole research effort into the new research centre, but that in practice this policy is a hindrance in attracting government grants and in dealing with national orders. But a major proportion of the £2-4 million being spent on research by Brown, Boveri would still be channelled into the new centre, he said, leaving perhaps 30 per cent of the total research budget to be divided between smaller research departments in France and West Germany.

Parliament in Britain

Enzyme Detergents

THE Home Office is conducting enquiries into possible harmful effects of enzyme washing powders, and it will decide on the basis of these enquiries whether any action is necessary. This was announced by the Joint Under Secretary of State, Mr Merlyn Rees, who also said that a few members of the public have complained that they have been adversely affected by these powders. (Written answer, January 19.)

Education Expenditure

PUBLIC expenditure on education, in real terms, rose on average by about 6 per cent a year between 1958–59 and 1968–69. Mr Edward Short, Secretary of State for Education and Science, gave this estimate in reply to a question from Mr David Lane, but he said that technical problems prevent a comparative estimate of educational expenditure being made. He therefore could not give an estimate for the increase in public expenditure on primary education, secondary education, further education or university education during the past decade. Mr Short also said that although raising the school leaving age to sixteen would not require more teachers it would cost about £13·5 million a year. (Written answer, January 23.)

Oral Contraceptives

THE Committee on the Safety of Drugs is reviewing the arrangements for conveying its views about adverse reactions to drugs to the professions concerned. This assurance was given by Mr Richard Crossman, Secretary of State for Social Services, after Mr Laurence Pavitt had expressed concern that major decisions of the committee, such as the advice on oral contraceptives, reach pharmacists via the national newspapers. Baroness Summerskill had previously provided a good example of the extreme reactions that have followed from the scare over harmful effects of oral contraceptives. She asked the government to issue instructions that all contraceptive pills should be withdrawn from the market because the United States has withdrawn the oestrogen-free contraceptive Normenal. Baroness Llewelyn-Davies of Hastoe said, however, that the government sees no justification for withdrawing all oral contraceptives from the market, and Baroness Gaitskill suggested that Baroness Summerskill lacked a sense of proportion in asking for this extreme measure. Baroness Birk also pointed out that if the government were panicked into withdrawing all contraceptive pills, the increase in deaths arising from pregnancy or abortions would be greater than the number of deaths from side effects of the pill, and she suggested that the anwer is to put more money into research to find a safer pill. (Written answers, January 23, and oral answers, Lords, January 22.)

Government R and D Savings

DR ERNEST DAVIES, Joint Parliamentary Secretary to the Ministry of Technology, said that reductions will be made in expenditure on civil nuclear and aerospace research, and development in AEA and Mintech establishments. Existing projects are not expected to be cut back, however. Government research and development is estimated to cost £66·8 million in 1971–72, compared with £71 million in 1969–70. (Written answers, January 19.)

Miscellaneous Intelligence

MR ROBERT GRAVES, the poet, has a bone to pick with science. "My main objection to science," he explains in the current issue of *Impact of Science on Society*, "is that it has spoilt the relation between the sexes. . . . Science and technology have interfered with natural sexual expression by making men and women no longer sure of themselves as men and women. . . . (They) have diminished the romantic relationship . . . and all but destroyed the pleasure and joy of sex, which is where everything good in life starts." Scientists who are mortified by this plangent indictment may take heart at the equally unrestrained pronouncement delivered in the same journal by Miró: "Scientists reveal nature's secrets as we artists do, but from another angle. Those who reflect and explore belong to a superior race. They are the princes . . . the real princes of today". To practise science, it seems, is to be roundly misunderstood on all sides, but better perhaps to be thought a Mrs Grundy or one of nature's aristocrats than to be ignored altogether.

IF any of the social sciences is a science, social anthropology is, but its rigour seems to depend on the long period of introspection that intervenes between studying the tribe and writing up the results. Articles in the current issue of *Man*, for example, are based on fieldwork carried out among the Limba in 1963–64, in the Coimbatore District of Madras State in 1965–66, and in Arnhem Land in 1965.

THE brave new image of the British Post Office has received so severe a tarnishing that it seems scarcely fair to drag even an ancient skeleton from its cupboard. But an article in the July 3, 1926, issue of *Nature* is too topical to wait its turn in *100 Years Ago*. In that week, *Nature*'s intrepid reporter visited the rooms of a Mr J. L. Baird in Upper St Martin's Lane, London WC, and was agreeably surprised to see the progress he had made in the problem of "seeing by telegraph" or television. "It is natural that Mr Baird and his partner, Captain Hutchinson, should contemplate a great future for television. Every possessor of a 'televisor' will be in a position to see on his screen the performers in operas and plays as well as hearing them. The new discovery will in no way interfere with the ordinary British broadcasting. The Post Office officials, seeing the probable advent of a new British industry, regard the scheme with *benevolent neutrality*." Let the faces of all servants of the NRDC blush pillar box red at thought of it.

FUTUROLOGY, it seems, is just wishful thinking after all. Almost the only surprising prediction of *Medicine in the 1990's*, a 'Delphi' method forecast produced by the Office of Health Economics, is that "the large international drug companies will develop greater political awareness, so that they may be able, for example, to exert considerable influence in the framing of national regulations for the control of medicines. . . . The dangers of state participation as a stifling influence on competition and innovation are all recognized in the advanced countries of the Western World". Nobody would guess it, but the Office of Health Economics was founded and is supported by the Association of British Pharmaceutical Industry.

University Rubs Shoulders with Industry

from our Social Medicine Correspondent

Newcastle upon Tyne, January

TWENTY-FIVE years ago the Department of Industrial Health was set up at the University of Newcastle upon Tyne (then King's College, University of Durham) with the aid of a £40,000 grant from the Nuffield Foundation. Housed, to begin with, in the medical school and staffed by a skeleton team of twelve, the department has since grown under the guidance of Professor R. C. Browne into a large and active assembly of semi-autonomous sections, inconveniently divided between the medical school and an elegant row of buildings less than a quarter of a mile away. In spite of the increasing teaching load, applied research continues to receive heavy emphasis and it is refreshing to see the way in which medical and non-medical staff work harmoniously together.

In addition to university financing, now approaching £50,000 a year, the department has also received generous support from the Science and Medical Research Councils, the National Coal Board, the Central Electricity Generating Board and the Nuffield Provincial Hospitals Trust among others. The largest grant so far—£200,000—has come from the Department of Health and Social Security. Made over to the department in late 1969, the grant will make possible the setting up of a new Medical Care Research Unit, which is to be jointly directed by Professor D. J. Newell, currently head of the department's medical statistics section, and Dr John H. Walton. The general interests of the unit will be directed towards problems inherent in the unification of health services: attempts will be made to establish norms in the provision of medical care and the response to its provision; to determine the pattern and efficiency of transfer between different sources of medical care; and to investigate the relationship of preventive, medical and social care, particularly in childhood. Work currently in progress in the medical statistics section includes a statistical analysis of the causes and methods of treatment of low-back pain—part of a multi-centre trial coordinated by Professor Newell. As well as carrying out research, the section's staff provides a consulting service for the design and analysis of clinical trials and medical surveys in the medical school and teaching hospitals.

Professor R. C. Browne, an expert on coal miners' pneumoconiosis, is head of the Department of Industrial Health.

Dr J. Steel heads the active and dual functioning occupational hygiene section. On the one hand, research is carried out into the various problems linked up with health and hygiene in industry. For example, much effort is concentrated on predicting the health risk to welders and burners who are exposed to fumes containing oxides of the toxic elements copper, zinc, nickel and cobalt which result from the decomposition of surface coatings during application of intense heat. These elements can cause, among other things, metal fume fever and metal poisoning. As a result of this work, the section has acquired a national role for the pre-testing of paints and electrodes before manufacturers put the products on the market. Another current line of research is the development of a sensitive method for detecting lead poisoning among workers using small samples of blood. Current methods require 5–10 ml. of blood. By looking at the way in which lead is in part organically bound to blood and urine, Dr Steel hopes to be able to predict susceptibility to lead poisoning in certain persons.

The section also tackled particular problems for local industries on a fee-for-service basis, as part of the North of England Industrial Health Service. This service, which is based in the Department of Industrial Health, has its own management committee consisting of representatives of the university, management and the Trades Union Congress and is virtually self-supporting. Although most of the work is done on a contract or consultative basis, some firms have joined as members, paying so much a head. This entitles them to advice on any matter relating to health at work and they also receive a regular visit from one of the service's medical officers. A new feature of the service is the launching this month, in Washington New Town, an industrial estate, of a group occupational health service under which an appointed nurse will make daily visits to member firms on the estate to administer first aid and to help in social and welfare matters. She will be backed up by a medical officer and may in future be joined by staff offering physiotherapy, chiropody and ophthalmic services.

Dr R. I. McCallum is currently perfecting a technique for measuring directly the amount of antimony trioxide in the lungs of process workers using an iodine radioactive isotope and a scintillation counter. Antimony pneumoconiosis, which is more of an inconvenience than a serious clinical problem, affects workers in one factory in the north-east, but the detection technique can be applied equally well to measuring tin in the lungs—a more common hazard. Dr McCallum is attempting to induce antimony pneumoconiosis in cats so that the amount of the element measured in living lungs can be compared with the amount present at autopsy as measured by, for example, atomic absorption spectroscopy. This will indicate the accuracy of the X-ray method.

Two other aspects of the department's varied research programme include an investigation into the effects on the lungs of breathing in radioactive xenon—headed by Dr H. L. Leathart—and a continued ergonomic study of industrial component inspection using a conveyor belt. This study is being conducted by Mrs Judy Lion.

Also housed in the department is the Decompression Sickness Registry, directed by Dr P. D. Griffiths. Although the Medical Research Council grant supporting the registry is made to Professor D. N. Walder, in the Department of Surgery, who is concerned with the significance of gas micronuclei in the aetiology of decompression sickness (see *Nature*, **222**, 251; 1969), the records and radiographs of thousands of men who have worked in compressed air are kept in the department. So are the new decompression tables giving the most suitable length of time for decompression, which are being widely used in compressed air work on an experimental basis. Under these tables, a man working at 44–46 pounds per square inch—almost the limit for civil engineering work—is required to decompress for 270 minutes compared with the 127 minutes required under government tables. Working in close association with other members of the MRC Decompression Sickness Panel, Dr Griffiths and Dr McCallum periodically arrange for X-rays to be taken of the limbs of men in compressed air work in the hope of detecting, at an early stage, aseptic necrosis of the bones.

Growing Pains in British Universities

by our Education Correspondent

THE next few years could see major changes in the British system of higher education. The number of student places must double in the next ten years: that now seems to be recognized both by the government and the universities, and it is unlikely that the system will come through such expansion unchanged. But the changes will inevitably be accompanied by their fair share of arguments. Preliminary skirmishes have already been made—the Department of Education and Science, in October and December last year, discussed, with the Committee of Vice-Chancellors and with the Association of University Teachers, various ways to achieve the expansion as cheaply as possible. It seems likely, however, that both bodies will reject most of the proposals put forward, and Mr Gerald Fowler, Minister of State with responsibility for higher education, has already complained that academics are being hypersensitive to alleged threats to academic freedom.

The controversy has been brought to a head by the latest predictions of the demand for higher education in the 1970s. Using the Robbins basis of relating entry to higher education with numbers of school leavers, the ministry predicts that 437,000 students will be engaged in higher education in 1971–72, 557,000 in 1976–77 and 727,000 in 1981–82. It suggests, however, that colleges of education will only increase their intake by about 20,000 in the next ten years, and the universities and further education establishments will therefore bear the brunt of the expansion. Such an expansion will require about a 7 per cent annual increase in student numbers, and it is unlikely that expenditure on higher education will be allowed to grow at the same rate. Faced with the demand for places outstripping the available resources, Mr Fowler has been casting around for ways to reduce the costs per student, and it is this which has stirred up the rumblings in the universities.

Analysis of the Department of Education and Science's figures for 1959–60 to 1967–68 suggests, however, that the government may already be reducing the costs per student. Fig. 1 shows that expenditure on the universities rose at about the same rate as student numbers between 1959 and 1964. But after 1965, when the Colleges of Advanced Technology were given university status, costs rose less sharply than student numbers. Even if these trends were continued, it is doubtful whether it would effect the saving which Mr Fowler wants, and moreover, expenditure on new buildings will inevitably tend to push costs up. For one thing, expansion of this order would require that several new universities must be established. It is reasonable to expect that existing institutions can do no more than treble in the next decade (only Reading and Strathclyde have done this in the past ten years), and most universities believe that about 12,000 is the maximum size that they could achieve without becoming completely impersonal establishments. Even if existing universities expand as quickly and as far as possible, the expansion would therefore fall short of the target for 1980.

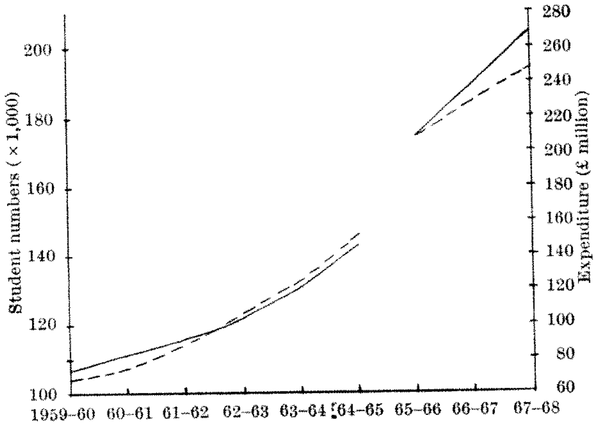

Fig. 1. Student numbers and university expenditure, 1959-68. ———, Student numbers; — — — —, university expenditure.

Some change in the system therefore seems inevitable, and the Department of Education and Science has suggested thirteen proposals to the vice-chancellors and the AUT for their consideration. Individual vice-chancellors will submit their own views to the Vice-Chancellors Committee probably early in February, and the AUT has set up a working party to formulate a policy for the universities in the 1970s. This policy will be presented to an extraordinary council meeting probably in March. At least twelve of the thirteen points are likely to be rejected by both bodies.

The proposals which seem to have caused the most concern are those which seek to alter the length of degree courses and the number of terms in a year. Among the points put to the vice-chancellors were proposals for replacing the present three-year courses with two-year courses of four terms a year, and for introducing a "box and cox" arrangement, in which the university timetable would be arranged in such a way that two sets of students could be taught in the same year. A similar arrangement is at present being operated by some colleges, one set of students being taught when the other is on vacation or industrial training. The vice-chancellors maintain, however, that alteration of the university year would inevitably reduce the time available for research and would place an intolerable burden on teaching staff. Sir Derman Christopherson, chairman of the Committee of Vice-Chancellors, speaking at the North of England Education Conference on January 9, also maintained that the three-year degree course and the present low drop-out rate would become more important in the future.

The Department of Education and Science also canvassed the possibility of student loans and of increasing the percentage of students living at home as measures likely to effect some reduction of cost, but both these suggestions will be bound to antagonize the National Union of Students, and it seems that the Association of University Teachers and the Vice-Chancellors would also oppose them. Sir Derman Christopherson, for example, said that students and their parents are already finding about £20 million a year towards making up their grants, and that simple commercial loans would tend to restrict higher education to those who could afford to pay for it. Professor Michael Swann, vice-chancellor of Edinburgh University, commenting on this, said that loans would not save very much money, but he suggests that neither students nor staff are as violently opposed to their introduction as is usually claimed.

Unless the number of staff increases at the same rate as the number of students in higher education, the staff/student ratio will inevitably suffer, and this is an aspect of the proposed expansion which seems to alarm many academics. The ratio in British universities, about 1 : 8 or 9, is, however, much lower than in most other countries, and Sir Derman hinted at the Northern Education Conference that he is prepared to see it raised slightly. He suggested, for example, that some departments could accept more students without parallel staff increases and without loss of quality. Professor Swann also suggests that if research facilities were expanded at the same rate as student intake, then some deterioration in research quality may be unavoidable. He therefore sees the higher education system developing more along the lines of the American system, with postgraduate schools becoming further removed from undergraduate teaching, but he indicated that he thought this to be a step in the wrong direction.

None of the proposals put to the vice-chancellors suggests that the government has altered its thinking on the binary system in higher education. One proposal did suggest, however, that there should be more sharing of resources between the universities and the polytechnics, and this is unlikely to be opposed by the vice-chancellors or by the AUT. There are indications, however, that the universities may be prepared to see the binary system eroded away. Sir Derman told the Northern Education Conference that "the separation of the education and training of most teachers from that of other students is an unsatisfactory arrangement which ought to be brought to an end as soon as possible", and he suggested that colleges of education should open their doors to students taking general degree courses, courses in social services and possibly science courses as well.

The AUT is likely to oppose the binary system outright. Like the National Union of Students, it sees the system as wasteful of resources, and it is bound to perpetuate the elitism of the universities. The AUT working party on policy for the universities in the 1970s suggested to the AUT annual council in December that an expanded University Grants Committee should distribute capital and recurrent finance to universities, polytechnics and in due course to colleges of education. A very similar system was proposed by the Select Committee on Education and Science last year, when it suggested that a Higher Education Commission should finance all sectors of higher education. But the government has given no indication that it intends to act on the Select Committee report, and indeed, maintaining the binary system seems to be central to its thinking on higher education expansion.

In a speech to the NUS Universities Conference on January 6, Mr Jack Straw, NUS president, argued that expansion is absolutely vital, and that the NUS regards the figures for student numbers in 1980 as a low basic minimum. The NUS also believes that the binary system should go, and Mr Straw argued for comprehensive institutions of higher education to be established. These institutions, called "polyversities", should provide a variety of courses, as wide as the universities, the polytechnics and the colleges of education combined, and they should accommodate both full and part-time students.

Both the NUS and the AUT are, however, less explicit about where the necessary finance should be found. Indeed, Mr Straw throws that problem back at the government by suggesting that it is not the duty of a pressure group like the NUS to do the work of the Treasury. He maintained at the Northern Universities Conference, however, that Britain lags behind most other advanced countries in an international league table of education expenditure. Using 1962–63 figures, Mr Straw said that the USSR spends about 8 per cent of its GNP on education, Japan, Holland and Canada each spend about 7 per cent and the United States spends about 6·3 per cent. Britain, on the other hand, devotes only about 5·8 per cent of its GNP to education. Mr Straw therefore suggests that the government is throwing a "smokescreen of panic" over the whole issue, and that the proposed expansion would do no more than bring Britain into line with other countries.

Although it seems that there is to be considerable controversy about the means of achieving the proposed expansion in higher education, both the government and the universities accept that it is necessary, and that doubling the numbers of students will not necessarily cause a deterioration of standards. Sir Derman Christopherson maintains that standards have been rising during the 1960s, although student numbers increased at an unprecedented rate, and Mr Fowler said that the doctrine that "more means worse" is patently untrue if one looks at the experience of other countries or of Britain during the past decade. If the projected figures for student intake in the 1970s are not met, competition for places in 1980 would be even stiffer than it is now, and the proportion of students undergoing some form of post-school education would be well below that of most other advanced countries. Moreover, even if provision in higher education were made for everybody who has minimum entry requirements now, Britain still would not have a mass higher education system equivalent to that in the United States.

Signs of Change at UGC

THE shortage of funds of which British academics have been complaining in the past year seems now to be real enough to have caused an actual decline in the cost of university education. This is apparent from the latest Annual Survey (for 1968–69) of the University Grants Committee (HMSO, 4*s*), which shows that in terms of 1967–68 prices, the cost of educating a full-time student fell from its peak of £900 a year in 1966–67 to £877 a year in 1968–69. The cost of paying academics has decreased steadily for the past four years, and now amounts to £357 per student per year, chiefly because of the slow increase of the ratio of students to staff, which is now greater than at any time since 1962 even if the British ratio remains, as the UGC reminds its pensioners.

The UGC is now half-way through the most turbulent quinquennium for a long time. The new report is the first to be presented by the new chairman, Mr Kenneth Berrill, who succeeded Sir John Wolfenden in January 1969. The quinquennium has already seen the controversy about the report of the Prices and Incomes Board on academic pay (December 1968), a strike by university technicians, a running battle (or skirmish) between the UGC and the universities over attempts to assess the productivity of academic people, the decision that the accounts of universities should be open to inspection by the government's inspector, the Comptroller General, and the perpetual quarrel about money. The new survey looks all these issues in the face but seems to dodge altogether more important issues of public policy—the relationship between the universities and the polytechnics. Nobody will take offence.

The intervention of the Prices and Incomes Board has clearly sharpened the aim of the Association of University Teachers to participate in formal machinery for the negotiation of salaries, although it seems clear that the question has not yet been settled of whom the AUT should negotiate with. The UGC is the obvious adversary, but everybody knows that it does not have the power to summon up the money needed to settle pay increases which may be forced on it, yet negotiation directly with the Treasury, which really holds the purse-strings, would undermine the doctrine of the autonomy of the university system. In default of a solution, the Prices and Incomes Board has been retained as referee, and a pay settlement based on data soon to be available will be back-dated to the beginning of the current academic year.

The UGC continues to provide funds for schemes which foster collaboration between universities and industry—many of the 38 grants now current (which will cost £190,000 in the current year) are for training courses in subjects such as cryogenics and food engineering, but three universities (Bath, Heriot-Watt and Dundee) have been blessed with industrial liaison officers while others have acquired lecturers in subjects such as management. These grants are only available for periods of three years, and it is laid down that the Science Research Council will often be involved in the making of decisions about new courses.

A kind of raffle among universities seems to have succeeded in increasing the number of places for teacher trainers in university departments of education by about 250—the UGC says there has been a good response to its scheme for paying to universities willing to increase their effort in teacher training sums of money which are multiples of £2,500 in each of the last two years of the quinquennium. There has been a similar success with even smaller sums of money as prizes in the provision of 150 extra places for psychiatric social workers, but management education remains a running sore—the two schools at Manchester and London are financed through the Foundation for Management Education, which is in turn dependent on subscriptions from private business and the government, but the UGC now calculates that there will be a rapid growth of its own responsibilities for management education at other universities. Outsiders will marvel that the two systems seem destined for indefinite co-existence.

If the UGC is a little too obviously anxious not to give offence in what it has to say about medical education, there is a robust if modest declaration of more support for marine biology, one of the chief features of which will be the setting up of the Scottish Marine Biology Association at Millport as a common university facility under the Natural Environment Research Council when the present staff moves into its new premises.

On the administration of university finance, the UGC is plainly (and rightly) proud of its scheme to devise a computer model of the university system so as to help with the allocation of funds, but a little nervous in its account of how it has rejected the advice of the Committee of Vice-Chancellors that at the beginning of future financial quinquennia, universities should be told all at once how much they will have to spend. The UGC argues that the first of the five years should be dealt with by means of a provisional settlement, although it does undertake to provide estimates of the likely size of the student population. The committee says that it has taken the opportunity provided by the government decision that local authorities will not in future be expected to help in financing awards to postgraduate students to set up, jointly with the research councils, a Committee on the Co-ordination of Postgraduate Awards.•

NEWS AND VIEWS

Up or Down?

THE assertion of the report of the Royal Commission on Population in 1949 that there would be "a substantial decline in the number of births over the next 15 years" has often been contrasted with the rise in the number of births in Great Britain during the 1950s.

How far has the science of population projection progressed in the 20 years since such estimates were first made? This question must be in the mind of anyone reading the article on recent changes in the birth rate of England and Wales by Eric Thompson, chief statistician of the Research and Intelligence Unit of the Greater London Council, in the current issue of *Family Planning* (**18**, No. 4; 1970). Thompson discusses the decline in the number of births in the past 5 years and the assumptions made about this decline by the Government Actuary in preparing the official population projections for England and Wales to the year 2001. In preparing the projections based on mid-1968, the Registrar-General commented that the post-1964 downward trend seemed to be slowing and was regarded as a temporary aberration in a secular increase. Thompson maintains that this is not so and that recently births have returned to the post-1964 downward trend.

The decline in the number of births since 1964—about 8 per cent in the 5 years to 1969—has been unexpected. Most of the variables which influence the number of births have been moving in ways which would lead to an expectation of increasing births. The number of women aged 20 to 29 increased by 11 per cent between 1964 and 1968 and will increase to 30 per cent over the 1964 figure by the mid-1980s. If the birth rate had remained constant at its 1964 level, this increase in the number of women in the most fertile age group would have led to a total of births in 1969 about 15 per cent greater than that which actually occurred. Age at marriage is decreasing, and because more than 90 per cent of births occur within marriage, other things being equal, this increases the percentage of women in the fertile age groups "at risk" of pregnancy. Changes in the proportion of women married at any particular age will have a short term effect on the birth rate because the range of potential changes is obviously circumscribed at both ends of the age range, more especially at the younger ages, but changes in the mean completed family size of marriages contracted at different times can have a more profound effect on the total of births.

The downward trend in the number of births forced a revaluation of the assumptions about mean completed family size for marriages recently contracted and still to be contracted. In particular, the positive differential in mean completed family size for marriages contracted at an early age (under 20) has been reduced because fertility at early ages has not continued to increase as it did during the past decade. There seems to be a convergence with the decreasing fertility of older ages. Thompson wonders whether the next set of projections should incorporate a more substantial narrowing of the early marriage–late marriage fertility differential, and questions whether it is correct to assume any increase in mean completed family size for current marriages.

It is hard to escape from the fact that the 5 year decline in the number of births is really too short a period on which to base any conclusive arguments. The reduced number of children born during 1964–69 is, however, a fact and must have an effect on the future age structure, and, from about 1984 onwards, on the level of future births. The reduction in the strength of the relationship between early marriage and high fertility seems to be the key to the enigma of the current pattern of number of births. Detailed studies alone will reveal the motivation behind this trend and it is important for assessing the future number of births to discover whether this relationship will soon stabilize somewhere near current levels, or whether the decline will continue until the marriage age differential in completed family size becomes much less marked than at present.

SEYFERT GALAXIES

A Cornucopia of Matter

by our Astronomy Correspondent

SEYFERT galaxies with their extraordinarily bright and unusual nuclei could easily be intermediaries between quasars and normal galaxies. Indeed, part of the evidence is that even superficially normal galaxies such as the Milky Way have a hint of abnormality about them. Yet it is far from settled in which direction the evolution is going. Obviously the more that can be found out about Seyferts the better, and in the current issue of *Astrophysical Journal* Kurt Anderson and Robert Kraft of Lick Observatory present evidence that matter is being ejected from the nucleus of the Seyfert galaxy NGC 4151 (**158**, 859; 1969).

They have shown that the nucleus of NGC 4151 seems to be losing mass at a rate which raises questions about where it is all coming from. Making several reasonable assumptions Anderson and Kraft find that the mass loss is something between 10 and 1,000 solar masses per year, but how nature would provide such an apparently inexhaustible cornucopia of matter, they say, remains decidedly unclear. Conceivably the mass loss of NGC 4151 could pose the same sort of problem as the energetics of the Crab Nebula which should have run down long ago.

The starting point of the study is a coudé spectrogram of the nucleus of the Seyfert obtained in a 5 hour exposure. It shows an absorption feature buried between two emission lines which was first recognized, it seems, by N. U. Mayall in 1934. Anderson and Kraft maintain that the feature between 3869 and 3889 Å is composed of three shell lines of HeI with velocities of -280, -550 and -840 km s^{-1} relative to the corresponding emission line, although there is reason to believe that the -840 km s^{-1} component is distorted by the neighbouring NeIII, Hζ and HeI emission lines so that it ought to be -970 km s^{-1}.

By making assumptions based on other features of the spectrum about the conditions of the clouds or shells of gas which are responsible for the three absorption lines, Anderson and Kraft are able to make estimates of the masses involved. One question is whether the outward flowing mass is moving with the escape velocity. Observations of other Seyfert galaxies suggest that the mass of the nucleus is between 10^8 and 10^{10} solar masses, and if the true value is in the upper half of this interval, 10^9 solar masses or more, probably none of the gas escapes. Yet the spectral lines which would be expected from gas falling back into the nucleus are absent. Assuming then that the observed material is being lost, something between 10 and 1,000 solar masses per year (depending on whether a cloud model or shell model applies) has to be accounted for. Clearly there is a lot to be explained.

STRUCTURE

Conflict in Mercury

by our Solid State Physics Correspondent

THE structure of the low temperature phase of solid mercury has been measured for the first time by X-ray diffraction and found to be different from the form predicted by non-local pseudopotential theory. J. S. Abell, A. G. Crocker and H. W. King (*Phil. Mag.*, **21**, 169; 1970) have produced a crystal sample of γ mercury by straining α mercury at 20 K, and have found four peaks in the diffraction pattern which could not have arisen from the face centred rhombohedral structure proposed by Weaire (*Phil. Mag.*, **18**, 213; 1968).

These results have both theoretical and experimental implications. Although only preliminary, they suggest that even the moderately sophisticated non-local pseudopotential used by Weaire is too inaccurate to distinguish between the two types of structure. The lattice spacings found by Abell *et al.* leave little room for doubt here, for even a generous variation of the axial angle cannot bring the theory into line. Experimentally, the chief difficulty was to strain the sample sufficiently to bring about the transformation to the γ phase and yet avoid fracture. A special jig was built for the purpose. The γ phase may well be thermodynamically stable at low temperatures, but the problem is to find some way of nucleating it which avoids generating too many common interfaces with the remaining α phase, thus producing severe strain in the lattice. The diffraction peaks showed the characteristic broadening of a strained lattice.

A detailed electron microscope study of the cubic form of solid nitrogen has thrown new light on the structure of this phase. J. A. Venables (*Phil. Mag.*, **21**, 147; 1970) has found that the grain boundaries move remarkably easily in α nitrogen, much more so than in oxygen or the rare gases, due partly, it is suggested, to the shape of the nitrogen molecules. Various imperfections were also observed, including dislocation loops and stacking faults. Venables points out that the free energy of stacking faults and twin boundaries may well be very dependent on temperature, implying that these defects might act as nucleation centres for the α–β phase transformation. Barrett suggested last year that small scale diffusion takes place across a large angle boundary in this transition, and Venables hints at the exciting possibility of actually observing this process in the electron microscope.

The *Philosophical Magazine* took on its new mantle as a Europhysics journal this month, but apart from an editorial hint of wider European participation on the board in the near future there was little sign of any new aspect to the journal. Indeed, of the thirty-six authors contributing to this issue, thirty are from Britain, five from North America and one from Africa. Perhaps the forthcoming meeting in Paris of the publications committee of the European Physical Society can inject some life into a policy which, although widely approved, is still felt by many to lack the credibility of a serious project (*Nature*, **224**, 1146; 1969).

MAGNETIC MONOPOLES

Sea Bed Search Sets New Limits

from our Cosmology Correspondent

NEW limits have been imposed on the possible abundance of free magnetic poles after a search for monopoles on the sea bed. In spite of the theoretical view, first proposed by P. A. M. Dirac (*Proc. Roy. Soc.*, A, **133**, 60; 1931), that the existence of free magnetic poles in nature is not only completely within the understanding of the laws of physics but also improves the symmetry of Maxwell's equations, no experimenter has been able to prepare or detect such free poles. The best limits on the existence of free monopoles have recently been reduced by a factor of several thousand by R. L. Fleischer *et al.* (*Phys. Rev.*, **184**, 1393; 1969), who have attempted to detect monopoles originating in cosmic rays using the Earth's oceans as a collecting tank for these energetic particles.

Having been thermalized in the atmosphere and oceans, suitably polarized poles would drift to the ocean bottom where they would be trapped in solid, magnetic material. The particular ferromanganese deposits used, taken from the mid-Atlantic, are particularly suitable because the slow rate at which this sediment was deposited means that a thickness of only 2·5 cm represents a continuous sample over at least 16 million years, while its magnetism will have prevented the escape of any poles. Removing any free poles present by means of a strong magnetic field, and detecting them by extending standard techniques for detecting cosmic ray particles, is, of course, a simple matter, but completely negative results were obtained by Fleischer *et al.* Because of the long time during which the collector—the sea bed—has been in operation, it is clear that the flux of free monopoles arriving at the Earth must be less than $4 \cdot 2 \times 10^{-18}$ cm^{-2} s^{-1}, up to an incident energy of $\sim 2 \times 10^{19}$ eV, a total of less than 1/2 monopole cm^{-2} during the entire age of the Earth.

A search for tracks left by monopoles in natural minerals has proved similarly unrewarding (R. L. Fleischer, P. B. Price and R. T. Woods, *Phys. Rev.*, **184**, 1398; 1969). The only remaining possibility for the existence of monopoles therefore seems to lie in the region of very high mass particles, but this must be a slender chance.

MOON

Mascons may be Plates

by our Astronomy Correspondent

THE mass concentrations beneath the lunar maria which P. M. Muller and W. L. Sjogren reported in 1968 may have a plate-like structure, according to M. F. Kane of the US Geological Survey in the *Journal of Geophysical Research* (**74**, 6579; 1969). This result, which should please people who have been saying that the mascons can be understood in terms of lava flows, was obtained from an analysis of the data for Mare Imbrium. The discovery of mascons came, of course, from detailed tracking of the lunar satellite Orbiter 5, and what Kane has done is to compare the form of the gravity anomaly over Imbrium with that expected for several mascon models.

In their discovery paper, Muller and Sjogren assumed rather arbitrarily a depth of 50 km for the mass concentrations, which meant that the Imbrium gravity anomaly required 20×10^{-6} lunar masses. For a nickel–iron sphere such as an asteroid this would correspond to a diameter of about 100 km, but it raises all sorts of problems about the survival of an object of that size striking the Moon.

Clearly other configurations are possible, and Kane claims that a plate-shaped mascon suits the data better. The problem with a spherical mascon is that although the fit to the data can be improved by bringing it closer to the surface, if the radius is to be kept equal to the depth of the centre the density becomes inordinately high. A suitable mascon, according to Kane, would be a 10 km thick layer at the surface, and if it were 400 km in diameter it need have a density excess of only 1 g cm^{-3} over its surroundings.

Unfortunately although the plate mascon is a good approximation near the centre of the gravity anomaly, it is as unsatisfactory as the spherical mascon elsewhere. Kane suspects that the answer might be found when the topography of the lunar surface is allowed for in the calculations. The ring of mountains around Imbrium, for example, has yet to be taken into account.

It is satisfying that this approach fits nicely with what people have been saying at Houston. Given that the maria were once vast lakes of lava, it seems possible that high density crystals might have sunk to the floor. This kind of structure is seen on the Earth, and density differences of the right size ought to be possible.

The principal implication of Kane's report, however, is that the distinction between a plate mascon and a spherical mascon is clearer in data taken from satellites nearer the surface. In the eighty orbits considered by Muller and Sjogren, the closest approach to the Moon by Orbiter 5 was 100 km. A 30 km orbit would be better for observing mascons. The point is that this kind of relatively simple satellite would give a lot of information about the interior of the Moon which, apart from pickings from deep impact craters, is otherwise inaccessible.

SEA FLOOR SPREADING

Is the Rate Constant ?

from our Geomagnetism Correspondent

THE magnetic evidence in favour of sea floor spreading was almost certainly the most important single geophysical result of the 1960s. The discovery that the pattern of magnetic anomalies normal to mid-oceanic ridges is similar to the polarity–time scale derived from continental rocks was the first significant support for sea floor spreading, and led to the first really convincing tectonic model for the Earth as a whole. But there are still a few details to clear up. For example, the rates of sea floor spreading calculated from almost all of the magnetic anomaly patterns covering the past 3 to 4 million years involve a decrease about two million years ago followed by an increase about 0·9 million years ago. Why should this be ?

Because the two discontinuities in the rate of spreading appear in all profiles from the Atlantic, Pacific and Indian Oceans, it has generally been assumed that they are real—as indeed they may be. The theory of plate tectonics, for example, which implies that all ridges are interrelated suggests that any change in spreading rate should be world-wide. But Emilia and Heinrichs are suspicious (*Science*, **166**, 1267; 1969). They point out that even if all ridges are related, it is unlikely that a universal discontinuity in the rate of spreading would be in the same sense at every ridge. Since this seems to be the case, it is much more likely that some of the accepted relations between the anomalies and the palaeomagnetic scale are incorrect. In this case, all spreading rate curves would contain the same error. They would all tell the same story, but it would be wrong.

The evidence that Emilia and Heinrichs adduce for this hypothesis is rather convincing. The first ocean magnetic anomalies were compared with the continental time scale before the discovery of the Gilsa event, which occurred about 1·65 million years ago. As a result, one particular anomaly was identified with the Olduvai event 1·96 million years ago, a practice which was continued even after the discovery of the Gilsa. But is this the correct thing to do ? It turns out that the spreading rate discontinuity 2 million years ago depends solely on this one identification. If the particular anomaly in question is now identified with the Gilsa event, the rate of spreading between 0·9 and 3·32 million years appears constant.

There is, of course, no *a priori* reason why the rate of spreading should be constant. But not only does it make the solution neater, it also ties up one or two other loose ends. Between the anomaly previously associated with the Olduvai event and the end of the

Gauss normal epoch, two further anomalies, designated *W* and *X*, frequently occur either as a pair close together or as a single anomaly. These have never been identified with any event or events on the continental scale. But if the rate of spreading between 0·9 and 3·32 million years is assumed constant, *W* turns out to have an average age of 1·99 million years, very close to the measured age of the Olduvai (1·96 million years). Anomaly *X*, with an average age of 2·3 million years, still remains unexplained but is less important in the sense that whenever only one anomaly appears in the region it is always *W*.

A further objection to the variable rate spreading interpretation is that the Gilsa event is left without a corresponding ocean magnetic anomaly. The important result, however, is that with the removal of the larger spreading rate discontinuity at 2 million years, the rate of spreading over the whole of the past 3·32 million years can be regarded as constant within experimental error—an altogether simpler solution which has the merit of explaining more of the observations than does variable rate spreading.

COMETS

OAO views Tago-Sato-Kosaka

by our Astronomy Correspondent

INTERESTING data continue to flow down the telemetry channels from the Orbiting Astronomical Observatory (OAO 2) which NASA launched in December 1968. By a happy chance, the brightest comet for several years has now appeared in the sky, and the OAO is being used to secure the first observations of a comet in the ultraviolet. This follows surprising results obtained by the OAO last year and released by the Americans in December (*Nature*, **224**, 1058; 1969) which seem to show that a few galaxies are unexpectedly bright in the ultraviolet.

Ultraviolet light below about 3000 Å is, of course, absorbed in the atmosphere, which among other things makes the important Lyman α line of hydrogen (1216 Å) inaccessible from the ground. With orbiting ultraviolet telescopes now available in the OAO, one of the results should be a better knowledge of the distribution of hydrogen in space.

In this spirit NASA announced last week that Lyman α observations of Tago-Sato-Kosaka by the University of Wisconsin instruments on OAO 2 show that the comet is surrounded by a cloud of hydrogen gas which is said to be comparable in size to the Sun. The hydrogen is presumably being ejected from the comet by solar heating, and will be interpreted in terms of Whipple's "icy-conglomerate" theory. This has it that the nucleus of a comet is made up of mineral particles bound up in a matrix of frozen gases such as water and ammonia—a flying gravel bank, in other words. Some of the gases vaporize when the comet approaches the Sun, to form a cloud known as the coma, but the size of the coma is small compared with the cloud of hydrogen which is now reported.

Following the usual practice, Tago–Sato–Kosaka is named after the three Japanese amateurs who independently discovered it on October 10 last year. (The Japanese have of course become dab hands at spotting undiscovered comets.) By December the comet was visible by eye in the southern hemisphere, moving north, but it is now retreating from the Sun and unlikely to be visible by eye into February. On February 2 it will be in Aries, near Alpha Arietis, at about magnitude five—the naked eye limit.

The Wisconsin instruments acquired Tago–Sato–Kosaka on January 14, and the plan is to follow the hydrogen cloud for as long as possible. The chief experimenter is Dr Arthur D. Code, and the schedule seems to be to observe the comet for 10 per cent of each 100 minute orbit.

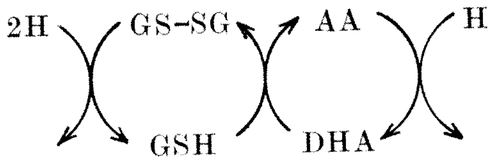
CELL DIVISION

Retine for Inhibition

from our Cytogenetics Correspondent

THE suggestion that dehydroascorbic acid is an inhibitor of cell division is a recent contribution to the discussion of how this process is controlled. Cells of a living organism may be actively dividing or they may be quiescent. How is the transition from one state to the other brought about? And how do cancer cells differ in their regulation of cell division? The task of answering these questions is formidable. One line of attack has been opened up by Szent-Györgyi and his colleagues. They argue that two regulators of division are involved; there is an inhibitor, "retine", and a promoter, "promine" (*Science*, **149**, 34; 1965). Szent-Györgyi's group identified retine as a keto-aldehyde, the simplest member of which is methylglyoxal. Keto-aldehydes are good electron acceptors and inhibit cell division and their effect can be reversed by thiols (molecules with —SH groups) which are good electron donors and so behave as promines (Együd, *Currents Mod. Biol.*, **1**, 14; 1967 and **2**, 128; 1968). These properties led Szent-Györgyi to propose (*Science*, **161**, 988; 1968) that the decision as to whether a cell would divide or not was controlled by the relative balance of retine and promine molecules. Stimuli to cell division, such as wounding of a tissue, cause the removal of retine molecules. In cancer cells it may be that retine is not produced and so the biochemistry of the cell favours cell division.

Much work remains to be done to support such concepts. Now, J. A. Edgar joins the fray with more ideas (*Experientia*, **25**, 1514; 1969). He accepts Szent-Györgyi's scheme but suggests that dehydroascorbic acid (DHA) may be a retine substance. DHA is widely found in animal and plant cells; it is an electron acceptor and is reversibly associated with ascorbic acid (AA). The reaction DHA⇄AA is mediated by glutathione (GSH), an electron donor that for many years has been thought to be implicated with cell division, in the following way



Edgar summarizes a large body of evidence which indicates that the balance between GSH and DHA may control the ability of cells to divide. For example, in plants it has been found that in cells leaving the dormant state (as in seed germination) the amount of DHA decreases while the amount of AA and GSH increases. Furthermore, in tissue induced to grow by the plant hormone indolyl-3-acetic acid a similar state of affairs is found. In animal tumours DHA has been found to be an inhibitor of growth, and some neoplastic cells seem to be deficient in DHA.

Another of Edgar's proposals is that in animal cells a balance of DHA and AA, with AA in excess, could control collagen synthesis, for one step in this process is rate-limited by AA. In this way collagen production would be strictly coordinated with the growth of the tissue.

Some crystal gazers believe that cancer will be controlled by the end of the century, and it may be that electron transfers between retine and promine molecules hold the key to the control of cell division.

NUCLEIC ACIDS

Hybridization and Satellite DNA

from our Cell Biology Correspondent

SINCE 1961 the technique of nucleic acid hybridization has been progressively refined to increase its resolution and range of usefulness, but until recently it has always involved the use of extracted nucleic acids. In theory, at least, if hybridization could be performed with nucleic acids denatured *in situ* this would permit the intracellular localization of specific classes of DNA and RNA. Last year, the rival groups of Gall, Birnstiel and Amaldi devised methods for partially realizing this potential. They all showed that isolated RNA can be made to hybridize with denatured intracellular RNA. Pardue and Gall (*Proc. US Nat. Acad. Sci.*, **64**, 600; 1969) have taken the technique one step further by hybridizing labelled DNA of *Xenopus* oocytes, from which ribosomal DNA had been removed, with denatured DNA of pachytene oocyte chromosomes and nuclei.

With the meiotic cells the labelled DNA was found bound to virtually all the chromosomes, but the experiments with the oocyte interphase nuclei prove the specificity of the hybridization. During oogenesis a cytologically distinct cap appears in the nuclei which contains the amplified ribosomal DNA, about 70 per cent of the total nuclear DNA. Labelled DNA, from which ribosomal DNA has been removed, fails to bind to the cap but binds to the rest of the chromatin. Three other lines of evidence indicate that hybridization is specific: first, cells treated with deoxyribonuclease fail to hybridize with the test DNA; second, alkali denaturation of the cell DNA is essential for binding test DNA; and third, the hybridization can discriminate DNAs of different sources. Mouse satellite DNA will not, for example, hybridize with *Xenopus* DNA, or that of much more closely related species, denatured *in situ*.

Apparently Pardue and Gall have used this new technique to solve a long standing question, the localization of the highly reiterated mouse satellite DNA fraction. The function of this satellite DNA has always been obscure, reducing investigators to suggest, for example, that it may be involved in chromosome "housekeeping", but Pardue and Gall claim that it is localized in the centromeres. It may therefore play a role in chromosome pairing, and this may account for the curious properties of satellite DNA, not least its peculiar base sequence.

It is also clear from Smith's experiments (*J. Mol. Biol.*, **47**, 101; 1970) that chemical properties and intracellular localization are not the only distinguishing features of mouse satellite DNA. Infection of a confluent non-dividing culture of baby mouse cells with polyoma virus results in a cell population with synchronized DNA replication during which enough satellite DNA is replicated before replication of the rest of the DNA is really under way. In Smith's experiments, replication of satellite DNA was completed 11 to 17 hours after infection, while replication of the rest of the DNA began after about 16 hours. Moreover, autoradiographs showed that much of the early replicating DNA ended up in association with the nucleolus. Whether or not early replication of satellite DNA is a characteristic of polyoma infection rather than an inherent cell characteristic remains to be seen. If the first alternative proves to be the case it may have interesting implications for tumour virology, while if the second is correct why is centromeric DNA replicated before the rest of the chromosome ?

TRANSFER RNA

Pieces in the Jigsaw

from our Molecular Biology Correspondent

THE structure of transfer RNA will not, one imagines, be revealed to the impatient public in one blinding flash; rather illumination will come slowly by a process of trial and refinement. The first uncertain steps towards the interpretation of the X-ray patterns of tRNA crystals have already been taken. Groups at two laboratories have almost simultaneously published Patterson syntheses and arrived at essentially similar interpretations. From Wisconsin, Labanauskas *et al.* (*Science*, **166**, 1530; 1969) report analyses of two species, leucine tRNA from *E. coli* and formylmethionine tRNA from yeast.

As prepared, the crystals have respectively a tetragonal and a hexagonal lattice. The data indicate in each case the existence of a long segment of double helix, and the strategy has been to refine the fit progressively by reference to a model derived in an accompanying paper (Connors *et al.*, *ibid.*, 1528), based on low-angle X-ray scattering envelopes. These reflect an asymmetric molecule, and a good fit between the calculated and observed curves can be achieved by making two limbs of the cloverleaf—the terminal stem and the pseudouracil-containing loop—a continuous double helix; this is feasible, because in all of the numerous sequences so far reported there are no intervening unpaired bases at the junction. The two remaining paired segments can then be fitted to lie parallel with the long helix, thus leaving the molecule 85 Å long. The model seems to fit the X-ray diffraction data very well, though clearly other configurations of the two short limbs to fit both the scattering and diffraction data may be possible. Labanauskas *et al.* insist, however, that the evidence for a long helical segment lying along one of the crystal axes is very strong: the introduction of, for example, any deviation from the standard RNA helix dimensions causes the definition in the Patterson synthesis to disintegrate.

A Patterson function has also been constructed by

Kim and Rich (*ibid.*, 1621) for *E. coli* formylmethionine tRNA. This crystal has a different lattice, but again there is a single ridge of density indicating a long asymmetric molecule. From the lattice symmetry it can be deduced that there is a pairwise relation between molecules, the dimer being made up of overlapping monomers, each about 80 Å long. This indicates again that there must be an intramolecular alignment of double helices, and is altogether consistent with the model produced by the Wisconsin group.

Meanwhile, the accumulation of chemical data continues. Some strange results on the effects of modification of pseudouracil residues have now been unequivocally confirmed. Siddiqui *et al.* (*Biochem. Biophys. Res. Commun.*, **38**, 156; 1970) have substantiated that cyanoethylation causes not only loss of acceptor activity, but also a drastic change in conformation, reflected by a diminution in hypochromicity and large broadening of the melting profiles. Moreover, by working with *E. coli* formylmethionine tRNA, which contains only one pseudouracil, and chemically protecting the thiouracil, which is the only other base capable of reacting rapidly with the reagent in question, they have shown that the introduction of a three-carbon chain in the pseudouracil loop destroys the native conformation. This is consistent with the model of Connors *et al.*, in which the loop packs into the large groove of the long helix, most probably with substantial stacking of the bases, this being evidently disrupted when the three-carbon spanner is thrust in.

The search for the functional sites on the tRNA has made relatively little new progress. Cory and Marcker (*Europ. J. Biochem.*, **12**, 177; 1970) determined the sequence of an *E. coli* methionine tRNA in the hope that a comparison with the formylmethionine species might reveal the synthetase recognition site (for both are substrates for the same synthetase), and possibly that of the transformylase. The two sequences turn out, however, to be very different, and no significant regions of homology can be discerned. Abelson *et al.* (*J. Mol. Biol.*, **47**, 15; 1970) have located the single base substitutions in three mutants of tyrosine suppressor tRNA. The acceptor activity is found to be grossly reduced by substitution of an A for a paired G in the helical stem of the anticodon loop. Substitution of A for an unpaired G in the dihydro U loop does not inhibit charging, but interferes with the function after attachment to the ribosome. One cannot yet, of course, exclude an explanation in terms of structural disturbance rather than a bull's-eye on enzyme recognition sites.

ROOT NODULES

Making a Vital Protein

from our Microbiology Correspondent

THE site of synthesis of the haem of leghaemoglobin, the protein necessary for nitrogen fixation in the nodules of leguminous plants, has been traced to the bacterial component of the nodule (J. A. Cutting and H. M. Schulman, *Biochim. Biophys. Acta*, **192**, 486; 1969). Leghaemoglobin has long been recognized as a component of the symbiotic association between legumes and species of the soil bacterium *Rhizobium*, but its function and site of synthesis have remained something of a mystery.

Bergersen's group at the CSIRO in Canberra found that the bacteroids, enlarged forms of the bacteria, which are present in the active nodule, had an electron transport chain similar to that of the free living bacteria except for the lack of cytochrome *a*. The haem protein was suggested to function as an electron carrier in the bacteroid and was implicated in the reduction of nitrogen. The exact function of leghaemoglobin in nitrogen fixation remains to be clarified, but a direct role is clear from many reports of the correlation between its concentration and the fixing capacity of the nodule. Ineffective nodules cannot fix nitrogen and are distinguished by the absence of leghaemoglobin.

The results reported by Cutting and Schulman go a long way towards solving the problem of where the haem is synthesized. Although other investigators had found evidence of a system which synthesizes porphyrin in root nodules, Cutting and Schulman's approach was to fractionate soybean nodules and follow the synthesis of haem by each component. Haem synthesis in unfractionated breis (whole, crushed nodule) and particulate and cytoplasmic fractions was determined according to the degree of incorporation of δ-amino[4-^{14}C] levulinic acid. Compared with the unfractionated breis, the particulate and cytoplasmic fractions accounted for approximately 70–80 per cent and 2–3 per cent of the haem synthesized, while remixing these fractions completely restored the activity of the whole breis. Further analysis of the particulate fraction showed that it lacked plant mitochondrial activity and that bacteroids were the only recognizable particles present.

Finally, Cutting and Schulman demonstrated that a large portion of the haem synthesized by the bacteroids was incorporated into leghaemoglobin, the latter being confined to the plant cytoplasm which encloses the bacteroids. The stimulatory effect of the cytoplasmic fraction on haem synthesis might be due to the provision of haem acceptor molecules which could alleviate feedback inhibition by removing the haem, or to the augmentation of bacteroid enzymes by mitochondrial or soluble enzymes originating in the legume. Thus haem synthesis for leghaemoglobin has been shown to be a function of the bacteroids in the root nodule, and it is likely that one explanation of ineffective nodules is that haem synthesis is defective in the microbial symbiont.

GYNAECOLOGY

Abortions Made Safe

from our Social Medicine Correspondent

A SAFE, effective method of inducing therapeutic abortion by injection of prostaglandin $F_{2\alpha}$ is described in the current *Lancet* (ii, 157; 1970) by S. M. M. Karim and G. M. Filshie. Of fifteen patients in the ninth to twenty-second week of pregnancy who were intravenously infused at the rate of 50 μg of prostaglandin per min, abortion was successful in fourteen cases and complete in thirteen. There were no serious side effects, and no changes in pulse rate or blood pressure were observed. Seven women had diarrhoea, however, and three of these also vomited. All seven responded to treatment.

Thirteen prostaglandins have been isolated from human semen. Although prostaglandins E_1, E_2, $F_{1\alpha}$ and $F_{2\alpha}$ have been used for the induction of natural childbirth, this is the first time a prostaglandin has been used for termination of pregnancy in the first and second trimester. The advantages of the technique are that it is simple to carry out; there is no risk of exposing the uterus to possible trauma from operative procedures; and the risk of infection is minimized. Other advantages of infusion with prostaglandin F_2 are that it brings about a high proportion of complete abortions and seems to be equally effective in both the first and second trimester.

According to Karim and Filshie, after vaginal examination, a needle with stylet was inserted into the amniotic sac of each locally anaesthetized patient and a catheter was passed into the amniotic cavity through the needle, which was then withdrawn. A sterilized, diluted solution of prostaglandin $F_{2\alpha}$ (concentration 50 μg/ml.) was then continuously perfused until abortion was complete. An increase in the muscular tone of the uterus occurred within 1–3 min in each case, followed by regular and rhythmical contractions which resulted in abortion in fourteen cases. In ten women the foetus and placenta were expelled simultaneously, and in three cases the placenta was expelled after a delay of 3–7 h. In each of these women abortion was complete and no further treatment was necessary. There was one case of retained (but detached) placenta; this was removed by evacuation. Pregnancy was terminated in the only woman who failed to abort following perfusion, by intra-amniotic injection of a solution of sodium chloride. After abortion, each woman received 0·5 mg of ergometrine intramuscularly. Loss of blood was less than 50 ml. in thirteen women, and approximately 200 ml. in one woman.

The rate at which prostaglandin $F_{2\alpha}$ had to be infused in order to stimulate the uterus in the first and second trimester (50 μg/min) is much higher than that required to induce labour in women at or near term (4 μg/min). With the former high rate of infusion there is the disadvantage that there seems to be some stimulation of the smooth muscle of the gastro-intestinal tract, leading to diarrhoea and vomiting.

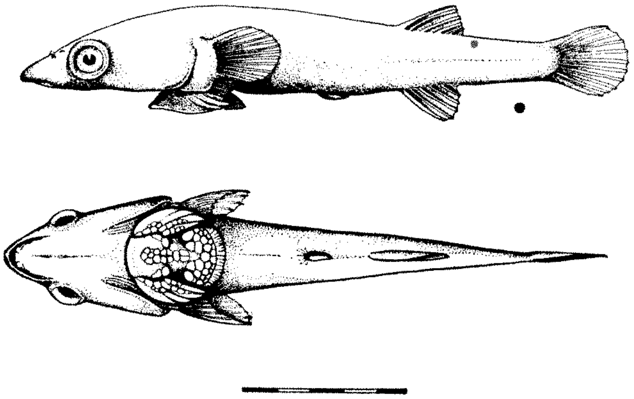
Karim and Filshie modestly say their experience is too limited to enable them to recommend routine use of prostaglandin $F_{2\alpha}$ in the termination of therapeutic pregnancies, but add that their results are very encouraging. As an addendum to their article they point out that they have successfully used another prostaglandin—E_2—at a low rate of perfusion—5 g/min—for inducing abortion in twelve women. None of them had diarrhoea.

ICHTHYOLOGY

More Clingfishes Found

from a Correspondent

CLINGFISHES, recently found on the coasts of South-West Africa and Angola (Penrith, in *Ann. S. Afric. Mus.*, **55**, 123; 1969), are small teleostean fishes which live chiefly in shallow coastal waters, many of them in the intertidal zone. They are particularly well adapted for life in the turbulent waters of the shore, for they possess a drastically modified pelvic fin complex forming a powerful sucker with which they cling to boulders. Although the shore is the stronghold of the group they are not confined to it, and several species are found in coastal waters down to depths of 22 m. Members of the subfamily Gobiesocinae have taken advantage of the sparsity of competition to colonize the smaller, swift flowing streams of the tropical New World and in some places they form an important component of the freshwater fish fauna. A specialized form, *Diademichthys lineatus*, is found in association with the Indo-Pacific echinoderm *Diadema*, living among its poisonous spines.



Eckloniaichthys scylliorhiniceps, a rather rare clingfish, which is one of the three species found on the coasts of South-West Africa and Angola. This fish is always found attached to algae.

Such specialization in a single group of fishes leads to speculation about their evolution. The zoogeography of a relatively small group like the clingfishes with rather restricted habitat requirements also makes them interesting. The problem, however, is that with their habit of insinuating themselves under boulders or in crevices they are often extremely difficult to find even on the shore. This has undoubtedly been reflected in available knowledge of their distribution in little explored regions. The coast of West Africa is a case in point, for in a world revision of the clingfishes, John C. Briggs (*Stanford Ichthyol. Bull.*, **6**; 1955) reported no specimens between Dakar and southern Africa, and only five species in the tropical eastern Atlantic. Collections in the region of Dakar and the Gold Coast, however, produced further specimens, and within 2 years of his revision Briggs was able to describe two previously unrecognized species, one of them a new genus (*Copeia*, No. 3, 204; 1957).

It is not surprising therefore that Penrith has announced the discovery of three species of clingfishes on the coasts of South-West Africa and Angola as a result of intensive collecting by the staff of the South African Museum. She also removes one stumbling block to the better understanding of clingfish distribution by showing that *Apletodon knysnaensis* Smith, 1964 (known from southern Africa only) is identical with *A. pellegrini* (Chabanaud, 1925), which was known from Dakar to Madeira. As in the space of 15 years the known clingfishes of the eastern tropical Atlantic have increased from five to nine species, it becomes apparent that far from being poorly represented there they are present in numbers. This could be cited as an example of the importance of adequate collecting to the progress of zoological studies involving taxonomy, distribution and geography.

Leipzig
Trade Fair

German
Democratic
Republic

Twice yearly centre of trade and technology Leipzig Trade Fair, reflecting the dynamic development of the German Democratic Rebublic, offers the buyer and the technical specialist alike an unmatched opportunity to see the world's latest achievements in design and technology. Leipzig Trade Fair, now over 800 years old, brings the goods of all the world together for all the world to see.

See you in Leipzig!

Leipzig Spring Fair 1970
March 1/March 10
Leipzig Autumn Fair 1970
August 30/September 6

A Visa will be issued on presentation of Fair Card and passport, at diplomatic and consular offices of the GDR, or at the Visa Bureaux on the state border of the GDR.

ACRYLIC
chromatography
columns

versatile inexpensive laboratory columns for chromatographic and gel filtration procedures employing aqueous solvents

Simple to use—unique patented design in acrylic and nylon with sintered plastics bed support.
Minimal dead space with low-volume connections. Diameters selected to produce cross-sectional area of 2, 4, 8, & 16 sq. cms.
Fixed or adjustable columns with or without jackets.
Standard lengths of 30, 60 and 90 cms.
Columns easily lengthened by joining.
Prompt delivery of standard columns from stock.
Preparative columns with bed volumes up to 50 litres are available to special order

Prices from **£5**

Caterpillars, Cabbages and Calories

Measuring the heat effect of a caterpillar eating a cabbage leaf presented no problems for the LKB Batch Microcalorimeter. Carried out as part of an investigation into the effects of insecticides, it proved the incredible sensitivity of the LKB instrument.

Though LKB do not see this as a regular application for the Batch Microcalorimeter, which has been designed primarily for liquid studies, the instrument is capable of measuring heat effects even smaller than those encountered in the "caterpillar experiment". The Batch Microcalorimeter will detect changes as small as one microcalorie.
The LKB Flow Microcalorimeter, which forms part of the system, can measure heat effects as small as one-tenth of a microcalorie per second.
This extreme sensitivity makes the LKB Microcalorimeters powerful analytical tools for studying short or long-term reactions of microscopic organisms such as enzymes and bacteria.
Simple to operate, requiring no special skills, providing fast results.

Write today for our illustrated booklet, which gives information about applications, and operational details of this unique system.

British Rail Advanced Passenger Train

by

S. JONES

British Railways Board,
222 Marylebone Road,
London NW1

During the past six years British Rail has carried out a thorough study of the problems of high speed transport. The result is a design incorporating improved acceleration, braking and suspension that makes possible speeds of 150 miles per hour. The first such trains are due to go into service in 1974.

UNLIKE other forms of transport the railways have not benefited greatly from recent scientific progress. Although many attempts have been made, railway speeds much in excess of 100 mph, for example, have been difficult to achieve in acceptable economic terms. This is, of course, not to deny the value of improvements embodied in railways such as the electrified Midland line out of Euston. There are many reasons for this slow progress. The varying pressures of defence needs have played a very important part. And the development of high speed surface transport involves difficulties which are not easy to overcome using a rail network conceived and built well over 100 years ago when conditions were very different. There is, however, a technical difficulty which probably more than any other has inhibited the increase in speeds of railway vehicles. This is a form of dynamic instability arising from the guidance of the railway lines.

Guidance is generally achieved in railways by fixing each pair of wheels solidly on a common axle and by providing the wheels with conical treads, the outer diameters being smaller than the inner diameters. The flanges on the wheels give an additional form of guidance which comes into play when guidance by the treads breaks down, for example, on a sharp curve. The contact between the flange and the rail wheels, which results in slip and wear, is minimized by the proper design of track layout and vehicle suspension. The guiding effect of the treads comes into play when a wheelset moves laterally across a pair of rails from the symmetrical position; the rolling diameter of the wheel further from the central position is then larger than the rolling diameter of the wheel nearer the centre. In consequence, for geometrical reasons, as the wheelset rolls forward it moves laterally back to the central position, overshooting, returning, and executing a sinusoidal motion of constant wavelength.

In practice the motion of the disturbed wheelset generally departs from a uniform sinusoid for several reasons. At low speeds, that is, when the inertial effects can be ignored, the sinusoidal motion rapidly decays to the mean steady state uniform motion of translation along the track because frictional effects absorb the energy of lateral oscillation. At high speeds the inertia of the wheelset calls into play substantial tangential forces at the interface between wheel and rail. These tread forces give rise to tangential creep (that is, incipient slip) which opposes the process of decay in the sinusoidal motion and if large enough can lead to a run-away process of increasing amplitude of oscillation ultimately contained by the flanges striking the edges of the rails. This effect is known as hunting and can be regarded as an instability arising from the feedback process in the guiding mechanism. The mechanism of creep is an essential link in the feedback chain.

This phenomenon of instability has been known for some time. For example, F. W. Carter described it as early as 1922 in his book *Railway Electric Traction*. Further, the general nature of instability arising from feedback in guidance has been extensively analysed in defence work during and after the Second World War. It is only relatively recently, however, that adequate effort and resources have been brought to bear to solve the peculiar difficulties of the railway problem.

Dynamic Study

Some seven years ago British Railways established a small team to make a thorough study of this phenomenon. The difficulties it encountered arose mostly from the application to practical railway vehicles with the many degrees of freedom involved and the gross non-linearities that are present. A linearized small-disturbance analysis was developed which together with analogue and digital computer facilities, small-scale model work on roller rigs, full-scale roller rigs and instrumented test runs on the track has resulted in a body of knowledge making possible prediction of the dynamic behaviour of practical railway vehicles. Further, design criteria have been developed for the design of vehicles capable of running stably at high speeds. A brief outline of this work was presented by A. H. Wickens to the American Society of Mechanical Engineers in December 1968. A series of four-wheel high speed test vehicles has been designed and constructed and run on track at the maximum track speed permissible (100 mph) and on a roller rig at 140 mph. Their dynamic behaviour has been in close agreement with prediction and has established confidence in the theoretical basis of design. Fig. 1 illustrates the latest of this series, High Speed Freight Vehicle, MK.4 (HSFV4).

An important parameter in the design of a railway vehicle is the conicity of the wheel treads (or effective conicity if the wheel treads have a curved profile in the axial plane). High conicity gives good guidance but with a proneness to dynamic instability at low speed. On the other hand, low conicity gives stabler running but poor guidance with frequent flange contact and excessive wear. And however the treads of wheels are first manufactured,

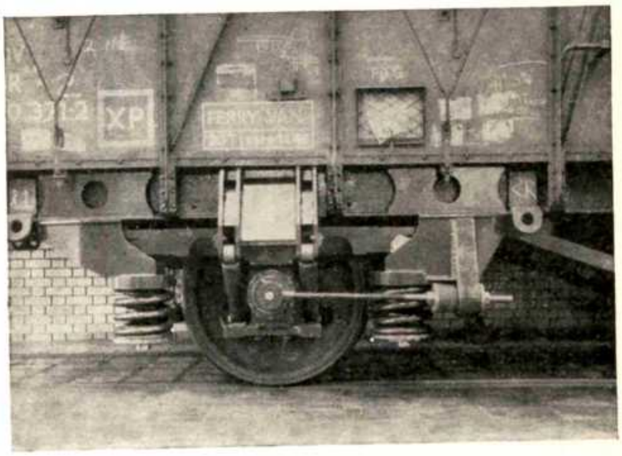

Fig. 1. The latest high speed test vehicle.

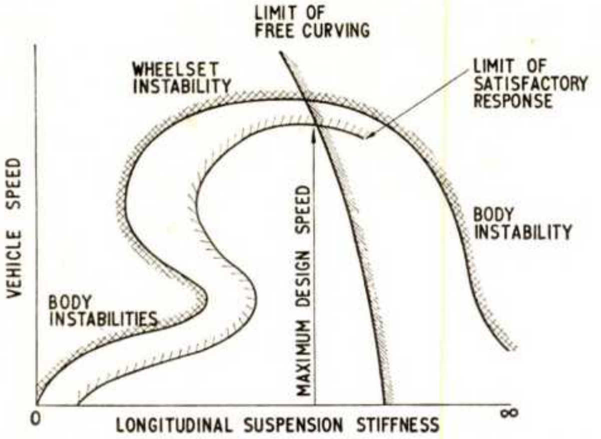

Fig. 2. Variation of stability with the speed of the vehicle and longitudinal suspension stiffness. The numerical values on the two axes will vary with the sophistication of the design. For the advanced passenger train mark I a speed of 200 mph is in the stable region.

they ultimately wear to a common tread shape characterized by a curved profile; additional wear then is to a smaller wheel with a similar profile. The maximum effective conicity of such a tread is high, its actual value then being dependent on the profile of the rail at its point of contact with the wheel. Economic considerations therefore demand a wheel profile sufficiently coned to provide adequate guidance with, if possible, a stable worn profile and a suspension system designed for stable running at all commercially desirable speeds. The HSFV series of vehicles are designed for wheels with such stable worn wheel treads.

The analysis of the dynamics of railway vehicles involves a large number of simultaneous equations and many stiffness, damping and inertial parameters. Stability at high speed is not achieved with a unique solution but by the acceptable choice of several parameters. Fig. 2, for example, illustrates the boundary stabilities as functions of vehicle speed and suspension stiffnesses. Limits are imposed by the need for lateral stability, the need to guide without flange contact around a curve and the need to provide an optimum response to imperfections in the track. These three criteria enclose an area of stable running which it is the objective of the design engineer to achieve.

An important consequence of the analysis of the stability problem of railway vehicles was the realization that the maximum speed of stable running was determined by the vehicle—and in particular its suspension characteristics—and not by the track. This concept leads to the idea that existing good main line track can be used for faster running with little or no change to the existing track provided the vehicles are adequately designed to be stable at these higher speeds. The economic consequences seemed to be so important that the matter was pursued further and so the idea of the advanced passenger train was born.

Advanced Passenger Train

The term "Advanced Passenger Train" is a registered name and relates to trains with certain specific design features. The train, shown in Fig. 3, is "advanced" primarily in the nature of the suspension which can be regarded as a direct descendant of the design philosophy developed in the dynamics studies I have described. The capacity to achieve economically stable running at high speeds presents a new incentive and new dimensions of design freedom. The passenger is rarely interested in speed as such. He is more concerned to reduce his travelling time, and so in a practical transport system it is desirable to increase the average speed by providing high accelerating and retarding characteristics and by the ability to run round bends at the fastest maximum speed. In addition the passenger desires a smooth, quiet and comfortable ride, and amenities and décor in keeping with the growing standards of material comfort available in general to the public. The suspension system must accordingly filter out frequencies particularly objectionable to the human body that arise from irregularities in the track. For economy of costs the design of the vehicle should be such as to reduce to a minimum the need for expensive maintenance.

Dynamic Behaviour

The advanced passenger train consists of an articulated set of eight or so vehicles, the two end cars being provided with motive power and those in between being trailer cars. The powered cars have six wheels and the trailer cars four wheels. The suspension design satisfies the criteria described briefly in the preceding section and the design aim is to provide stable running, in the first instance, of speeds up to 150 mph with a design stretch up to 200 mph (but the train will be operated initially at a maximum speed of 125 mph) and to provide optimum response to track irregularities. For this latter purpose considerable measurements have been made of the roughness of the track and the results expressed statistically in the form of a power spectrum. The suspension is designed as a

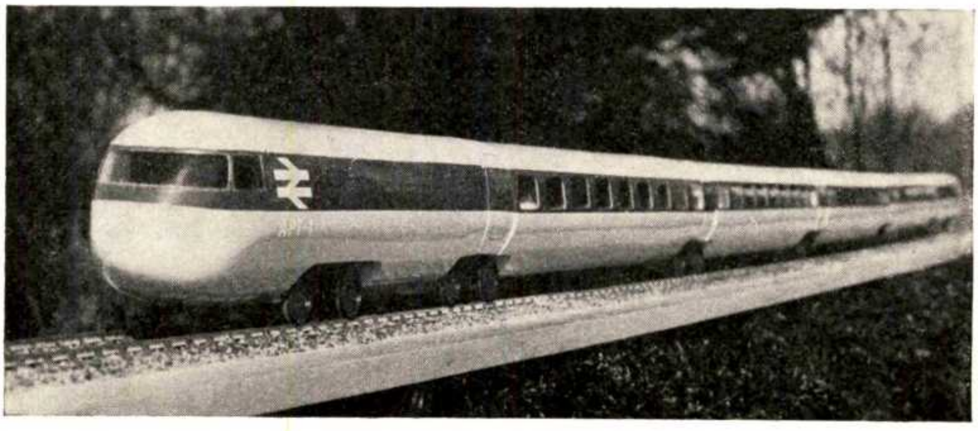

Fig. 3. The advanced passenger train.

mechanical filter to reduce to the minimum those frequencies arising from important track imperfections that are particularly objectionable to the passenger. The coaches are articulated and the suspension is designed to run without flange contact on all curves on the main lines of British railways.

Curving

The important limitation to the speed of a passenger vehicle negotiating a curve is the lateral acceleration imposed on the passengers. It is customary in railways to meet this limitation in part by canting the track on curves. The degree of cant should be sufficient to alleviate most of the lateral acceleration for high speed trains and yet not sufficient to be troublesome for stationary or slow moving trains.

The suspension of the APT is effectively pendular. The concept is not new and the objective is simply to provide a banking—or inward tilting—of the vehicle on curves, to nullify the effects of lateral acceleration on the passenger. In the steady state condition, that is, on a curve of constant radius, a free pendulum satisfies this criterion, but it does not in the transient conditions on a variable radius curve. For this reason, but more importantly to make the maximum use of the relatively small loading gauge of British Rail, the coach is not suspended freely above its centre of gravity but tilted by an active hydraulic suspension system which, sensing lateral accelerations, tilts the coach by the proper amount even in rapidly changing conditions. The effective centre of rotation is chosen so that the cross-sectional area swept out by the swinging coach over $\pm 9°$ is reduced to a minimum.

Acceleration Capability

Rapid acceleration is achieved by a high power-to-weight ratio. The structures of the APT are made of light alloy and as a consequence the structural weight per passenger seat is about half that achieved in conventional railway coaches. In fact it is reduced to a point where further lightening of the structure is prohibited by the need to maintain lateral stability to side winds. The designed axle loads are only about 11 tons each; the unsprung mass is also light. These two factors are of considerable importance in preserving the track from excessive punishment in high speed running.

The motive power is provided by gas turbines and it is proposed to use the automotive gas turbines now being developed by British Leyland. Four turbines, each of 300 nominal horse power, will drive the wheels of each power car. In addition a fifth gas turbine will be provided for domestic power supplies. The gas turbines will be installed so as to facilitate relatively easy removal from the body of the power car for maintenance or replacement.

Braking

The distances between fixed signals beside the tracks in a railway network are determined by the maximum speeds of the trains using the network. This follows from the braking distance that a train can achieve and the relationship between that braking distance and the speed of the train. If a high speed train like the APT is to use existing track and signalling equipment, it must have adequate braking facilities. The increased kinetic energy demands an energy absorption that increases as the square of the speed. The retarding force of the train for a given stopping distance also varies in proportion to the speed, so that the power dissipated by the brake increases as the cube of the speed. The considerable increase on brake requirements as speed increases eliminates the possibility of conventional rim brakes and a form of hydrokinetic brake is being developed to absorb the greater braking power required.

Ultimately, the brake capability is limited by the adhesion between the wheel and the rail. It is believed that the more stable running of the APT will give a greater mean adhesion at high speed than is customary with less stable vehicles. However that may be, development work is in hand to examine the practicability of various ways of increasing the coefficient of adhesion between wheel and rail. A plasma torch is being developed and early results are very promising. It is proposed to use this device, ahead of the driving wheels, to clean the rail surface at the point of contact with the wheel.

Development Programme

The advanced passenger train is being developed by the British Railways Board with the active and practical support of the Ministry of Transport. The conceptual design is now complete and rests on the extensive body of theoretical and experimental knowledge developed during the past six years.

During 1970 laboratory rig work will be undertaken on the power unit, the drive unit, the suspension unit, the braking system and the driver's control system. These units are now being designed in detail. At the same time power and trailer car bodies are being manufactured for an experimental train. It is planned to have the experimental train running on the track by the middle of 1971. This train will be used exclusively for experimental and development work and as the work proceeds the decision will be taken on the final specification and design of two prototype trains which are planned to be introduced into revenue earning service by 1974. The production of further trains will be determined during the progress of the work on the experimental and the prototype trains.

The attraction of the advanced passenger train is that it offers a fuller exploitation of the existing rail network of a good modern railway system with little or no additional investment in track. This is the reason for interest in the possibility of licensing the train abroad. The successful development and commercial exploitation of the train when demonstrated will raise questions of still further development which will then require decision and investment depending on the performance that is sought. The earliest investment decisions would be of a relatively minor kind, for example, the possible need to provide additional safety devices on the rails at points and crossings for the higher speeds and the advantage of smoothing out the sharper curves on main line track. Later decisions would be more important, concerning such matters as level crossings, tunnel entries, the movement of high speed trains through existing stations, new signalling techniques and further improvements to track alignment. From the technical point of view alone, speeds of, say, 300 mph are feasible, but questions of public policy and amenity have to be answered satisfactorily before such speeds can be implemented. It is important, however, to register the fact that in technical terms it seems feasible to contemplate speeds of this order along tracks which are not incompatible with much of the existing track and with many of the existing main line railway stations. This applies, for example, to surface links between air terminals and city centres as well as the longer distances between the main centres of population in Britain.

Diffusion in Embryogenesis

by
FRANCIS CRICK
Medical Research Council
Laboratory of Molecular Biology,
Hills Road, Cambridge

A simple order-of-magnitude calculation suggests that diffusion may be the underlying mechanism in establishing morphogenetic gradients in embryonic development.

> *It has been a great surprise and of considerable importance to find that most embryonic fields seem to involve distances of less than 100 cells, and often less than 50.*
> Professor Lewis Wolpert[1]

WHEN I read this sentence I was delighted because it seemed to confirm some conclusions I had come to on purely theoretical grounds[2]. It is an old idea that "gradients" are involved in embryological development—in fact, C. M. Child[3] in 1941 wrote a whole book on the subject. Many of the gradients to which Child referred seem more likely, in retrospect, to be the results of development rather than its cause. An outsider to embryology has the impression that in recent years gradients have become a dirty word. This is partly because of the failure to isolate unambiguously the molecules involved, whose concentration is presumed to constitute the gradient, and partly because a feeling has grown up that diffusion is not a fast enough mechanism for establishing gradients. In this article I aim to show that this fear is unfounded, and, on the contrary, that the known facts, sparse as they are, fit rather well to a mechanism based on diffusion. The problem can be stated in this way: what is the maximum distance over which a steady concentration gradient could plausibly be set up in the times available during the development of the embryo ?

The obvious model for setting up a simple gradient is illustrated in Fig. 1. At one end of a line of cells one postulates a source—a cell which produces the chemical (which I shall call a morphogen) and maintains it at a constant level. At the other end the extreme cell acts as a sink: that is, it destroys the molecule, holding the concentration at that point to a fixed low level. The morphogen can diffuse from one cell to another along the line of cells. After a time the system approaches a dynamic equilibrium, and it is easy to show that if the effective diffusion constant is everywhere the same, the concentration gradient will be linear.

Of course, real embryological structures will have three dimensions, but if for convenience we restrict ourselves to sheets of cells such as, for example, the insect epidermis[4] or the developing amphibian retina[5] the problem becomes two-dimensional. The source can be considered to be a line of cells (the line being perpendicular to the paper in Fig. 1) and similarly for the sink, thus reducing the problem to one dimension.

It is not difficult to calculate how long it would take to set up such a system, supposing that both the source and the sink are turned on at time zero. Diffusion is a random walk process, and the dimensions of the diffusion constant, D, are L^2T^{-1} (where L is length and T is time). This should be contrasted with a mechanism having a velocity (with dimensions LT^{-1}) as proposed, for example, by Goodwin and Cohen[6]. Because in diffusion the length enters as the square, pure diffusion processes are very rapid over rather short distances (say, the size of a cell) and very slow over long distances (say, the size of an organ).

The concentration approaches its final value asymptotically, so one must have some criterion for deciding whether the gradient at any time is sufficiently close to a straight line. I have arbitrarily taken the gradient to be effectively established when it is everywhere within ΔC of the final value, and chosen ΔC as 1 per cent of C_0 (C_0 is the maximum value at the origin). It would make little difference to the argument if ΔC were considered to have half this value.

The gradient might be set up in various ways. The result in each case can be expressed as

$$t = \frac{A\ (nl)^2}{D}$$

where t = time in seconds to set up the gradient; n = number of cells between source and sink; l = length of each cell, in cm; and D = diffusion constant, in cm^2 s^{-1}. A is a numerical constant, the exact value of which will depend on the way the gradient is developed.

Mathematically the simplest way is to start with zero concentration of the morphogen everywhere at time zero, and thereafter to maintain the source at concentration C_0 and the sink at concentration zero. This gives a value of A of 0·42. Biochemically more realistic models give values only a little larger than this, so a good general value for A would be 0·5. It was pointed out to me by Dr Aaron Klug that, if the initial concentration were uniformly $C_0/2$, the time required is reduced to a little less than one-quarter, and A will have a value of about 0·09. More realistic models of this general sort give values of A of, say, 0·15. The calculations of A were carried out by Mrs Mary Munro.

In what follows, I shall assume that A is 0·5 (the simple mechanism), but it should be remembered that the organism might be able to reduce this to about a third of this value.

The diffusion constant in water for all but the smallest molecules—provided they are roughly spherical—is inversely proportional to their mean radius, to a near approximation. Thus, increasing the molecular weight by a factor of 1,000, from, say, a small organic molecule such as ATP (mol. wt. 507) to a very large protein like polynucleotide polymerase (mol. wt. about $0·5 \times 10^6$) reduces the diffusion constant only by a factor of 10. Now it is reasonable to expect that the morphogen will diffuse rather rapidly, and should be able to pass fairly efficiently from cell to cell. It is also likely to be a rather specific molecule. For these reasons I doubt if morphogens will turn out to be large proteins or common ions[7] like K^+ or Na^+. An obvious choice would be an organic molecule of about the size of, say, cyclic AMP or a steroid. That is, with a molecular weight in the range 300 to 500. The diffusion constant[8] in water (at 20° C) for such a molecule is about 4 or 5×10^{-6} cm² s⁻¹. (The diffusion of salts like NaCl or KCl is about three or four times as fast as this.)

The inside of a cell is very far from being made of water, and one must estimate the effective diffusion constant within a cell. This amounts to estimating the effective viscosity. The cytoplasm being a concentrated mixture of molecules having a large variety of sizes, the relative viscosity will be considerably higher than water at the same temperature. For a small molecule, which can, as it were, slip between many of the other molecules, the effective viscosity is unlikely to be as big as the bulk viscosity of the cytoplasm (wherever that may be). It is difficult to make any precise estimate of the effective diffusion constant, which in any case may vary considerably between different types of cell. Allowing a factor of increase of viscosity of ×6 (corresponding to a sucrose solution 40 per cent by weight), which seems not unreasonable[9], would make the effective diffusion constant about $0{\cdot}8 \times 10^{-6}$ cm² s⁻¹.

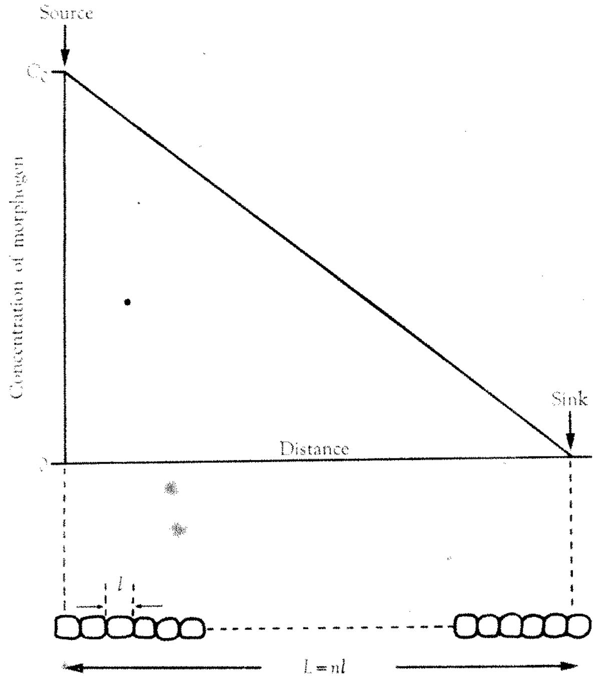

Fig. 1. To illustrate how a source and a sink can produce a linear gradient of concentration. Each cell in the line has length l cm. The distance between source and sink is L cm. Because n is the number of cells in the line, $L = nl$.

How does the morphogen get from cell to cell? It would seem inefficient to make all cell membranes easily permeable to it. To do this it would in any case have to be very small and rather hydrophobic[10]. Moreover, a high general permeability would allow the molecule to escape too easily from the tissue and this would not only disturb the gradient but possibly interfere in other parts of the organism. One is therefore driven to postulate a special mechanism which allows a relatively quick passage of the morphogen from one cell to another in the tissue of interest. Whether this involves tight junctions or other special structures remains to be seen.

Such a mechanism could be facilitated diffusion. This is characterized by being independent of energy, specific (usually stereospecific) and saturatable at high concentrations of the diffusing molecule. The passage of glucose through the membrane of a human red blood cell or an ascites tumour cell is believed to have this character.

At low concentrations (that is, far from saturation) the mechanism can be described by a permeability, P, measured in cm s⁻¹. It is easy to show that the effective diffusion constant, D', for our problem is given by $1/D' = 1/D + 1/Pl$, where l is the length of each cell in the direction of diffusion[11]. Thus, if D is $0{\cdot}8 \times 10^{-6}$ cm² s⁻¹ and $l = 10$ μm (say) we see that if the "resistance" to flow of the morphogen because of permeability between cells was equal to that due to diffusion within a cell, P would have to have the value 8×10^{-4} cm/second. This is a high value, but probably not impossibly high[12]. If we arbitrarily take P as about half this and D as before, we obtain $D' \simeq 0{\cdot}27 \times 10^{-6}$ cm s⁻¹.

We now need an experimental estimate of the time needed to set up a gradient. This is not easy to obtain. Most embryologists would feel that a day is too long. A minute seems far too short. A few hours would seem about right—Wolpert has suggested that between 5 to 10 h is not unreasonable for many of the well-studied cases (ref. 1, page 41). I shall assume a figure of 10^4 s (approximately 3 h), because some time must be allowed for the changes which take place after the gradient is set up.

Combining our formulae we obtain

$$t = An^2l^2\left(\frac{1}{D} + \frac{1}{Pl}\right)$$

and substituting the chosen values: $t = 10^4$ s, $A = 0{\cdot}5$, $l = 10$ μm, $D = 0{\cdot}8 \times 10^{-6}$ cm² s⁻¹, $P = 4 \times 10^{-4}$ cm s⁻¹ we obtain $n \simeq 70$ cells. If l were 30 μm, n would come to a little over thirty cells. Even allowing for the very approximate nature of the calculations, the agreement with the figures given in the quotation at the start of the article is striking. In broad outline what the calculation shows is that, for the times considered, distances or the order of a millimetre (or less) are possible, but distances of a centimetre are too great[13]. Of course, for organisms which develop very rapidly the distances would have to be smaller than a millimetre.

We can take it, then, that assuming the effective viscosity of cytoplasm has not been grossly underestimated, and provided there is a special mechanism to increase the rate of permeability of the morphogen between cells, there are many cases in embryology where the times and distances involved are quite compatible with a mechanism based on diffusion. It is important, however, to make two reservations. There may be special cases, involving setting up gradients quickly over large distances (of the order of several centimetres) which may require other mechanisms, such as the signalling devices suggested by Goodwin and Cohen[6]. Cases of "mushroom growth" (as, for example, the growth of mushroom) are unlikely to be due to diffusion alone. Secondly, in one's enthusiasm for diffusion, it is important to realize that the many other problems remain to be tackled. Even when the gradient has been set up the cell has to recognize it. Because at least in the insect integument the "gradient" appears to impose a polarity on those epidermal cells which become scales and bristles[14] the cells must have some additional mechanism (involving microtubules ?) to do this.

In the case of the amphibian eye the retinal ganglion cells must not only recognize the presumed gradient (so that they know where they are in the retina); each cell must also convey this information to the far end of its growing axon, so that it can make the connexion at the appropriate place on the optic tectum[5]. Moreover, there are likely to be subsidiary mechanisms to guide the growing bundle of nerves along the right path to the tectum.

In two brilliant articles published about ten years ago, Locke[15] showed that the pattern of wrinkles obtained on the adult cuticle of Rhodnius after operations on the earlier larval stages (usually the last larval stage) can only be explained by a "gradient" of some sort, running from one intersegmental membrane to the next, and repeating in successive segments. He showed convincingly that neither mechanical expansion alone, nor polarity alone, could explain the results. Dr Locke kindly sent us the original photographs of some of his material. Mrs Mary Munro and I, together with Dr Peter Lawrence, have attempted to fit these patterns to a pure diffusion model. Although, following Locke's arguments, the observed wrinkles have roughly the expected pattern, they differ in detail from the computed pattern. Moreover, various estimates of the diffusion constant disagree drastically. We are therefore currently exploring a model in which each cell in the epidermis attempts to maintain the concentration of the morphogen within itself to a previously preset level, determined soon after the gradient is first set up. This model, which has only one disposable parameter, is a much better fit with Locke's data. More elaborate hypotheses, within the basic diffusion framework, are also under consideration. It is important, therefore, not to approach these problems with too naïve a model[16].

Finally, one should emphasize that gradients are unlikely to command general acceptance until their biochemical basis is discovered experimentally, and that this may not prove an easy task. Mathematically minded biologists could well object that any theory which has the same mathematical formalism would necessarily fit the observed patterns, and that the agreement between the calculated and observed distances (on the diffusion theory sketched above) may only be coincidental. In spite of these possible objections it is my belief that mechanisms based on diffusion are not only plausible but rather probable. Nature usually has such difficulty evolving elaborate biochemical mechanisms (for example, those used in protein synthesis) that the underlying processes are often rather simple. If this approach serves to make the idea of diffusion gradients respectable to embryologists it will have served its purpose.

I thank my wife for drawing the figure, my colleagues, especially Dr Peter Lawrence and Mrs Mary Munro, for many helpful discussions, and Professors Lewis Wolpert and W. D. Stein for sending me information.

[6] Goodwin, B., and Cohen, M. H., *J. Theoret. Biol.*, **25**, 49 (1969).

[7] The mechanism for forming a source and a sink for ions also presents special problems, whereas for organic molecules rather simple enzymatic processes could do the trick.

[8] The effect of temperature on the viscosity of water does not seriously affect the calculations. Taking the viscosity of water (in arbitrary units) as 1·0 at 20° C, its value at 5° C is about $1\frac{1}{2}$ and at 39° C is close to 2/3.

[9] See, for example, a very ingenious fluorescent method used by Victor W. Burns (*Biochem. Biophys. Res. Commun.*, **37**, 1008; 1969) using a small organic molecule. He obtained a factor of about ×6 for Euglena. The figure for yeast was about twice this.

[10] Lieb, W. R., and Stein, W. D., *Nature*, **224**, 240 (1969).

[11] This assumes that the permeability is fairly evenly distributed over the cell membrane. If it were concentrated in a small patch the effective diffusion would be slower.

[12] For example, P for glucose in ascites cells at 37° C in about $4{\cdot}5 \times 10^{-4}$ cm/s (Kolber, A. R., and LeFevre, P. G., *J. Gen. Physiol.*, **50**, 1907; 1967), or in human red cells at 37° C about 1×10^{-4} cm/s (Millar, D. M., *Biophys. J.*, **5**, 407; 1965). Admittedly these are among the higher values of P known so far. See Stein, W. D., *The Movement of Molecules Across Cell Membranes*, chap. 4 (Academic Press, New York, 1967). It should be remembered that in going from one cell to the next the morphogen may have to cross two cell membranes.

[13] An upper limit can be calculated assuming that the morphogen is an ion, that it diffuses (at 37° C) in the cytoplasm as freely as in water, that the permeability between cells is so high that it does not slow down the process at all, and that the most efficient method is used to set up the gradient. The distance then comes to 1·5 cm, but I feel that this combination of assumptions is quite unrealistic.

[14] Piepho, H., *Naturwissenschaften*, **42**, 22 (1955); Lawrence, P. A., *J. Exp. Biol.*, **44**, 607 (1966).

[15] Locke, M., *J. Exp. Biol.*, **36**, 459 (1959); *J. Exp. Biol.*, **37**, 398 (1960).

[16] The present model could be elaborated by assuming two different morphogens, one having a gradient sloping from left to right, and the other with a gradient from right to left: on this model the position of a cell would be characterized by the ratio of its concentration of the two morphogens. This particular elaboration, however, would not significantly alter any of the arguments given in this article.

Restoration of In-phase Translation by an Unlinked Suppressor of a Frameshift Mutation in *Salmonella typhimurium*

by

JOSEPH YOURNO
SHIGEGI TANEMURA

Biology Department,
Brookhaven National Laboratory,
Upton, New York 11973

When carrying an unlinked suppressor, a frameshift mutant produces small quantities of wild-type protein.

UNTIL recently no frameshift mutations had been observed to respond to unlinked suppressors[1]. Two such frameshifts, both in *Salmonella typhimurium*, have now been described. Riyasaty and Atkins originally reported on the externally suppressible frameshift *tryA91* in the anthranilate synthetase gene of the tryptophan operon[2]. The other such frameshift, *hisD3018* in the histidinol dehydrogenase gene of the histidine operon, was isolated by Oeschger and Hartman after induction with the acridine derivative, ICR–191[3]. These frameshifts probably differ from one another in sign or base content as revealed by reversion response to selected mutagens[2–4]. Examination of histidinol dehydrogenase from several prototrophic double frameshift mutants has shown that the *hisD3018* frameshift is a +1 type, resulting from the inclusion of an extra C residue in mRNA (Fig. 5)[5,6]. Unlinked weak suppressors highly specific for *hisD3018* arise spontaneously and are induced at high frequency by ICR–191[3,4]. All *hisD3018sup* (suppressed mutant) strains examined produce very low levels of electrophoretically normal histidinol dehydrogenase conferring slow growth in the absence of histidine[4]. We present here further genetic evidence for such suppressors. Histidinol dehydrogenase from one *hisD3018sup* strain, produced at about 1 per cent of normal levels by our best calculations, has been purified to homogeneity and found to have the wild-type amino-acid sequence.

Genetic Evidence for Unlinked Suppressors

The *hisD3018* frameshift mutation is located in the operator proximal portion of the *hisD* gene[3]. This site is covered by the extensive deletion *his-2236* but recombines at very low frequency with the deletion *his-646* and at a higher frequency with the deletion *his-712* (Fig. 1, Table 1*A*). The following genetic tests confirm the presence of an unlinked suppressor in *hisD3018sup* isolates.

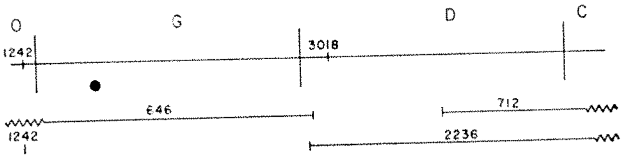

Fig. 1. Map site of the *hisD3018* frameshift. The deletions used for mapping, *hisGD646*, *hisDC2236* and *hisDCBHAFIE712*, are represented below.

All *hisD3018sup* strains, regardless of mutagenic origin, show frequencies of recombination with the aforementioned deletions characteristic of the *hisD3018* site, suggesting that these harbour the parent mutation along with an unlinked suppressor. When crossed into *hisD3018* as recipient these strains transduce the unlinked suppressor gene at high frequency, conferring weak prototrophy on the parent mutant. This is shown for two such strains in Table 1*A*.

A test diagnostic for the presence of suppressors of a mutation is the recovery of the original mutation. We therefore attempted to isolate *hisD3018* recombinants from *hisD3018sup* donors in crosses with the operator constitutive strain *hisO1242* as recipient. Selection was made for *hisO*+ or the closely linked polar *hisD3018* mutation at 43° on histidine-supplemented minimal agar, in which *hisO1242* cannot grow (see ref. 7). One hundred transductants from each cross were isolated and classified nutritionally as *hisO*+, *hisD* or other *his* genotypes, arising through mutation in the *hisO1242* recipient. The purified *hisD* isolates were tested for response to ICR-191 and NG both of which revert *hisD3018*[3,4]. Transductants resembling *hisD3018* were recovered at high frequency only from the *hisD3018sup* donors and the *hisD3018* donor control (Table 2). From each cross, six isolates testing as *hisD3018* were further examined and found to map as *hisD3018* and to be transducible to weak prototrophy at high frequency by a *hisD3018sup* donor (Table 1). Another method has also been used by D. Riddle and J. R. Roth (personal communication) to isolate *his3018* from *hisD3018sup* strains. Thus it is clear that the original *hisD3018* frameshift is maintained in the *hisD3018sup* strains and that prototrophy is the result of unlinked suppressors.

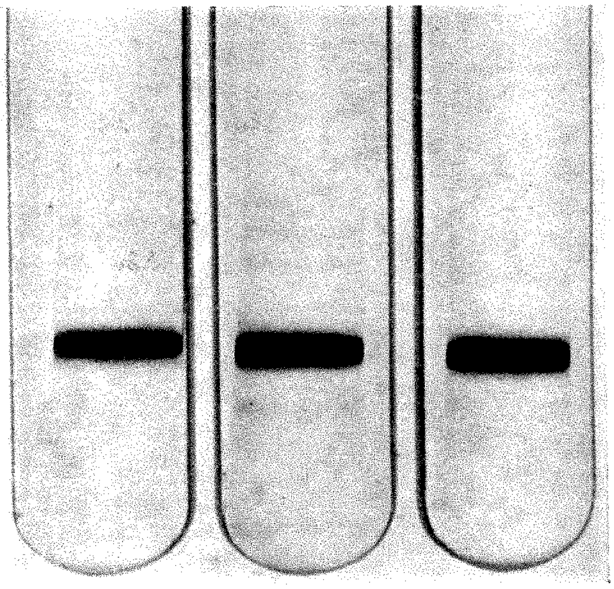

Fig. 2. Polyacrylamide gel electrophoresis of purified TR936 and wild-type histidinol dehydrogenase. The standard *p*H 9·5 system was used. From left to right: wild type, 60 μg; TR936, 60 μg; wild type, 30 μg + TR936, 30 μg.

To examine the specificity of suppression these suppressors were tested as donors with several *hisD* mutants of various types (classified by J. Greeb, J. Atkins and J. Loper; unpublished data) including the frameshifts *3029*, *2252* and *2550*, nonsense *2117*, *2120*, *2131* and *2186*, and missense *451*, *492*, *619* and *1742*. None gave a positive response, suggesting a high degree of specificity of these suppressors toward *hisD3018*.

Analysis of *hisD3018sup* Histidinol Dehydrogenase

The pivotal consideration in any analysis of enzyme produced at very low levels in a mutant cell is that the material isolated does not actually arise through otherwise insignificant background intragenic reversions, particularly if the enzymes of the divergent genotypes are not differentiable. The *hisO1242–hisD3018sup* strain,

† R1 is an intragenic reversion to wild-type[4].

‡ > 90 per cent small.

§ All values in parentheses are for a second experiment.

‖ Thirty-four plates tested for culture 1, twenty-one for culture 2.

¶ Grown on double enriched minimal medium.

TR936, constructed by D. Riddle and J. R. Roth, produces derepressed levels of histidinol dehydrogenase on histidine supplemented medium where the growth rate is increased to normal and selection for intragenic revertants is minimized. Cells of TR936 (10 kg wet weight), grown in two 1,000 l. batches on histidine supplemented double enriched medium, were supplied by R. G. Martin. Aliquots of each culture, taken immediately before harvesting, were tested for colony morphology and for transduction characteristics. On agar containing high concentrations of glucose derepressed strains such as *hisO1242* form wrinkled colonies while the highly polar *hisO1242–hisD3018sup* strains form smooth colonies (compare ref. 7). Of a total of more than 10,000 colonies, no wrinkled types formed by *hisD*$^+$ cells (intragenic revertants) were found. Cell counts were not higher on histidine supplemented plates. The level of contamination from reversions to *hisD3018sup*$^+$ (unsuppressed mutant) as well as to *hisD*$^+$ therefore seemed insignificant. Phage prepared from each culture transduced the outside marker control *leu-428* to large colony and *hisD3018* to small colony prototrophy, but produced no transductants with *his-2236* in conditions that should have yielded a total of at least 60,000 colonies with *hisD*$^+$ donors (Table 1*B*). On the other hand, the frequency of transduction of *hisD3018* to prototrophy was only 25 to 50 per cent of normal for TR936 with donor phage from both cultures. We are uncertain of the reason for this behaviour, but the plating tests mentioned above indicate it was not the result of loss of the suppressor gene.

Histidinol dehydrogenase from the TR936 cells was accordingly purified in lots of 1 kg at a time by the standard procedure[8] through the ammonium sulphate precipitation step. The preparations were then passed through either a 'Sephadex *G*-150' column, 10 × 100 cm, or a 'DEAE-Sephadex *A*-50' column, 10 × 25 cm, with the usual buffer systems[5,8]. The concentrated column eluates were combined and passed in alternating fashion through four 'Sephadex *G*-150' and four 'DEAE-Sephadex *A*-50' columns of successively smaller size and the enzyme was crystallized twice (compare ref. 8). TR936 (histidinol dehydrogenase) activity is so low as to be indeterminate in cruder fractions. The specific activity of crude extract enzyme was calculated from the purification data, with the wild-type as a standard, to be approximately 0·0022 units per mg protein. This level is about 1 per cent that of *hisO1242–hisD*$^+$ histidinol dehydrogenase from cells grown in similar conditions (0·26 units per mg protein) (R. G. Martin and J. Y., unpublished observations). The twice crystallized preparation had a specific activity of 11·1 units per mg protein, virtually identical to that of homogeneous wild-type enzyme[8]. We can conclude therefore that histidinol dehydrogenase synthesis in TR936 is about 1 per cent that of the *hisO1242–hisD*$^+$ strain, with the assumption that the histidine-grown TR936 cultures did not contain a sizable fraction of *sup*$^+$ cells. In any event, the level calculated for the total culture is 600-fold that attributable to potential wild-type contaminants, which, as we have shown here, could constitute a maximum of 0·0015 per cent of the cells.

Approximately 28 mg of purified TR936 enzyme was obtained, equivalent to a yield of 30 per cent of the starting activity. This enzyme was indistinguishable from a wild-type control in polyacrylamide gel electrophoresis at *p*H 9·5 (Fig. 2), and in amino-acid composition.

Tryptic peptide T26A of histidinol dehydrogenase is affected by the *hisD3018* frameshift[5]. The wild-type peptide is inseparable from peptide T26B on standard peptide maps. Because (1) the small amounts of TR936 enzyme available precluded examination of peptide T26A by methods more rigorous than peptide mapping, and (2) our working hypothesis was that this enzyme is

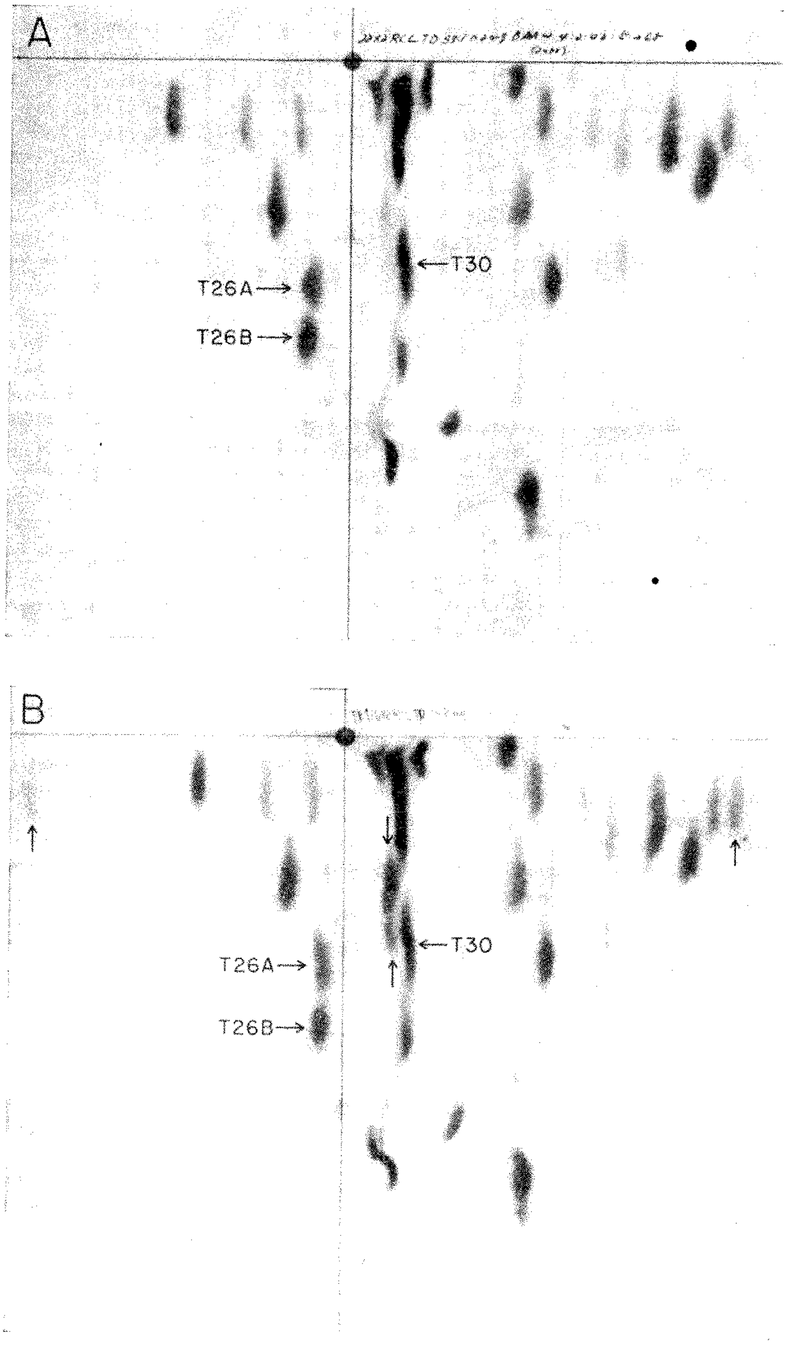

Fig. 3. Tryptic peptide maps of reduced carboxymethylated histidinol dehydrogenase. *A*, Wild type. *B*, TR936. Pertinent peptide spots are indicated by horizontal arrows. Peptides staining more strongly in the TR936 map are indicated by vertical arrows. These are occasionally much more intense in the wild-type as well and therefore seem unrelated to suppression.

wild-type in amino-acid sequence, we sought a chromatograph solvent which would effectively isolate wild-type T26A in peptide maps. Tryptic peptide maps prepared with butanol–pyridine–acetic acid–water (4 : 2 : 0·2 : 5) proved adequate and revealed that T26A of TR936 was present in the wild-type position (Fig. 3). The combined T26A spots from three peptide maps of TR936 digest, stained with the ninhydrin–collidine reagent[9], were solubilized in pyridine–water (1 : 1), then dried and hydrolysed in 6 M HCl as described previously[5]. The amino-acid composition of T26A from TR936 was indistinguishable from that of a wild-type control prepared in the same manner, even with respect to the levels of contamination observable (Table 3). The wild-type peptide has been shown to have the sequence Val-Thr-Pro-Glu-Glu-Ile-(Gly, Ala_4)-Arg (ref. 5). Tryptic peptide T30 of TR936 N-adjacent to T26A (ref. 10) was also wild-type in map location and amino-acid composition.

‡ Major observable contaminants given in parentheses.

These results strongly suggest that the suppressor gene is capable of restoring small amounts of histidinol dehydrogenase with a wild-type sequence in TR936 cells. To confirm this a method was developed for sequencing the critical section of the protein from T26A. From 12 mg of each tryptic digest, six peptide maps were prepared and stained lightly with 0·025 per cent ninhydrin in ethanol. Peptide T26A was thus detected with virtually no destruction of N-terminal valine, facilitating the subsequent Edman degradation. The pooled peptide, extracted in pyridine–water (1 : 1), was subjected to four steps of the subtractive Edman degradation. For TR936 T26A the sequence Val-Thr-Pro-Glu-(Glu, Ile, Gly, Ala_4)-Arg was unequivocably established for both the TR936 peptide and the wild-type control (Fig. 4). That wild-type glutamic acid residues, rather than glutamines, are present in TR936 T26A is indicated by its normal electrophoretic mobility at *p*H 6·5 (Fig. 3).

The suppressor state of TR936 must therefore involve modification of some component of the translation system so that the frameshifted region of *hisD3018* mRNA, containing an extra C residue, is translated in phase, producing an intact polypeptide chain of normal sequence (Fig. 5). Previous studies on missense suppression[11,12] and nonsense suppression[13,15] have established altered tRNA as the suppressor agent. Fink *et al.*[7] have shown that ICR compounds can induce unlinked suppressors of nonsense mutations in *S. typhimurium* and have proposed an addition–deletion mechanism at the level of tRNA. A similar suggestion has been made for ICR-induced nonsense suppressors in yeast[16]. Riyasaty and Atkins (ref. 2) have alluded to the possibility of suppression by tRNA in their study of the suppressible frameshift, *tryA91*. Although other mechanisms, such as those based on re-initiation of translation in a compensatory phase, may obtain in other systems[2,5], our results for *hisD3018* favour a model of low efficiency in-phase reading of the +1 frameshift by a suppressor tRNA. One appealing possibility is a suppressor tRNA with a quadruplet anticodon[5]. The fact that ICR-191 induced the *hisD3018* + 1 frameshift and is very effective in inducing unlinked suppressors[4] is consistent with such a mechanism. To produce wild-type enzyme this could occur at three possible quadruplet codon sites: (1) ACCC as threonine, (2) CCCU as proline, (3) UGA$^{A}_{G}$ as glutamic acid (Fig. 5*A*). The quadruplet anticodon for proline or threonine could originate in repair or replication of the tRNA gene by the same slippage mechanism[17] in a DNA segment of repeating GC pairs considered to have generated the *hisD3018* frameshift[5]. The *tryA91* frameshift may be a −1 type[2]. In terms of this model, suppression of *tryA91* could be mediated by a

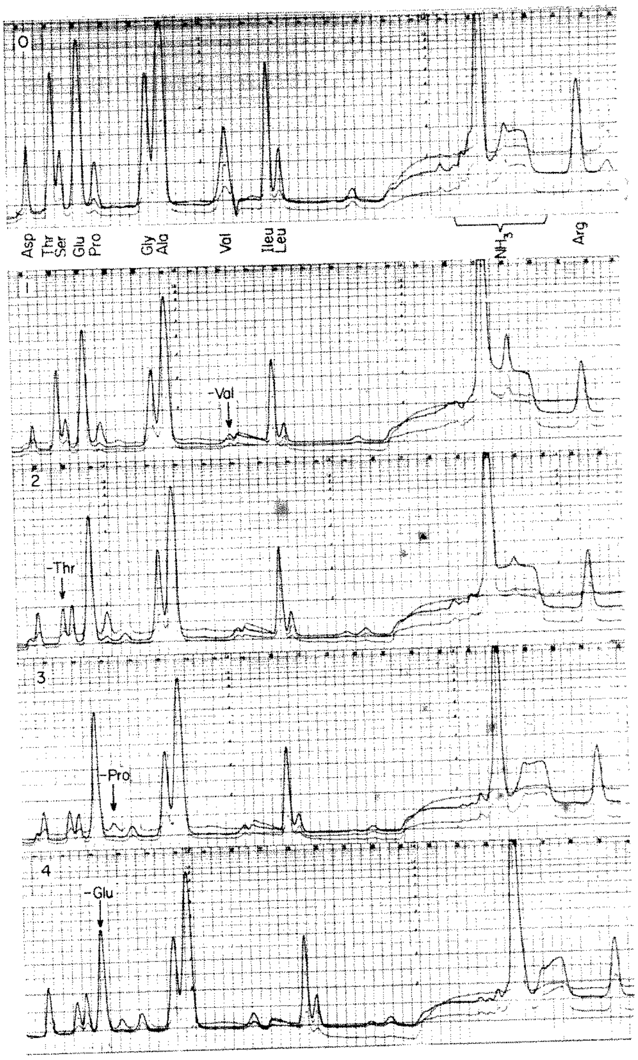

Fig. 4. Amino-acid composition and partial sequence of TR936 peptide T26A by Edman degradation. Shown are amino-acid analyser chromatograms of hydrolysates. The 570 nm line, and the 440 nm line for proline only, have been traced with Indian ink. Smaller peaks are accentuated on the logarithmic scale. 0, undegraded peptide 0·075 μmole analysed. See Table 3 for amino-acid composition. 1, 2, 3, 4, peptide after successive steps of the Edman degradation, about 0·040 μmoles analysed per step. The wild-type T26A control gave virtually identical results. See text for further details.

tRNA with a doublet anticodon. NG, and to a lesser extent ICR-191, induce unlinked suppressors of *tryA91*[2]. Both of these mutagens can delete single base pairs from DNA[3,5]. Another possibility is a suppressor tRNA with out of phase pairing properties imparted by alterations in tertiary structure induced by addition or deletion. Through distortion or steric hindrance such a tRNA might skip a base or slip when pairing with mRNA and thus correct the +1 frameshift of *hisD3018* (Fig. 5*B*). Given "wobble" pairing[18] at the third and fourth base pairs in codon–anticodon recognition, the number of possible *hisD3018* suppressor tRNA species is large.

In Fig. 5 it can be seen that a polar UGA codon[19,20] is generated in the +1 phase immediately after the frame-shifted segment of *hisD3018* mRNA. The UGA codon might well enhance the level of *hisD3018* suppression by impeding normal translation of mRNA in the +1 phase at the frameshifting site, thus allowing an inefficient suppressor tRNA to compete effectively in codon pairing.

Although there is less precedent, other components of the translation system, such as the ribosome, could be the site of suppression. Unlike many base substitution mutations[21] and typical of frameshifts[1], *hisD3018* is not phenotypically curable by streptomycin[3]. These observations, however, do not rule out a different suppressor site or mechanism at the ribosomal level

We thank our colleagues D. Riddle and J. R. Roth, who prepared strain TR936, and R. G. Martin, who provided large quantities of TR936 cells. We also thank J. R. Roth and P. E. Hartman for a critical reading of this manuscript. The research was carried out under the auspices of the US Atomic Energy Commission.

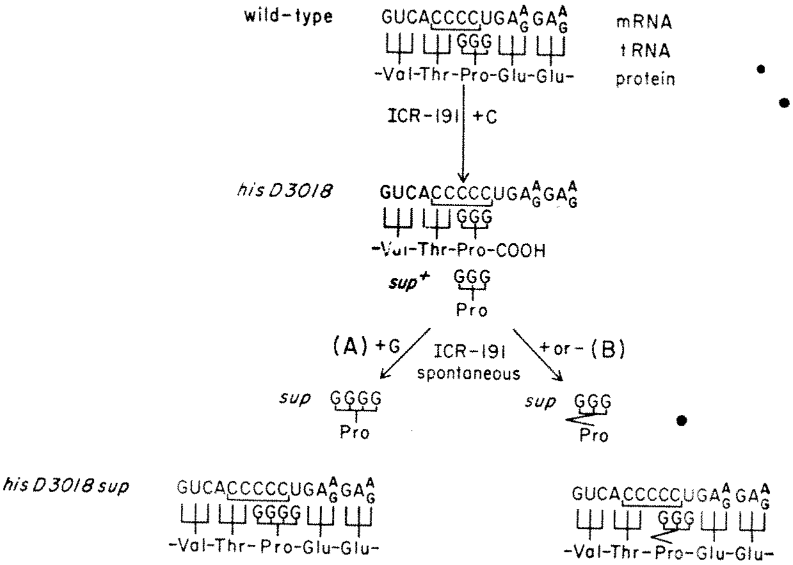

Fig. 5. Possible modes of *hisD3018* suppression. Aminoacyl-tRNAs are diagrammatically shown paired to their respective mRNA codons. The frameshifting properties of *hisD3018* result from the inclusion of an extra C residue in mRNA somewhere within the bracketed area. The chain-terminating codon, UGA, dictating formation of a polypeptide fragment with C-terminal proline, is generated in the +1 phase immediately after the frameshifting site in *hisD3018*. Suppression may occur as follows: *A*, a proline suppressor tRNA with the quadruplet anticodon GGGG restores in phase translation by pairing with the quadruplet CCCU; *B*, a conformationally altered proline suppressor tRNA with the normal triplet anticodon GGG skips a nucleotide or slips when pairing with the quadruplet CCCU.

Eye Dominance in the Visual Cortex

by

COLIN BLAKEMORE*

Neurosensory Laboratory,
School of Optometry,
University of California,
Berkeley, California 94720

The projection from the contralateral eye dominates the cat's visual cortex. Binocular neurones in any small region have their receptive fields more widely scattered over the ipsilateral retina than over the contralateral. Stereoscopic vision may depend on this difference in the two projections.

As far as we know, the fibres in the optic nerves of all primitive mammals cross over, or decussate, completely at the optic chiasma[1]. Each eye projects its information entirely to the opposite hemisphere of the brain. But in more advanced mammals with frontal eyes and therefore a considerable binocular visual field, a certain proportion of the retina on the temporal side sends its optic nerve fibres into the optic tract on the same side, and therefore to the ipsilateral hemisphere[2].

This process seems to go hand in hand with the development of binocular vision[3] and so furnishes the clue to why partial decussation occurs, for in an animal with frontal eyes the temporal retina of one eye is viewing the same region of space as the nasal retina of the other. Thus each hemisphere is concerned with information from the opposite half of the visual world, whether it comes from one eye in animals with lateral eyes or from part of both eyes.

---

* Present address: Physiological Laboratory, University of Cambridge.
† Present address: The Royal Prince Alfred Hospital, Camperdown 2050, NSW, Australia.

We are here concerned with the nature of the inputs from the two eyes to the striate area of the cat, a binocular animal whose brain has been intensively studied in recent years. How are signals in the primitive fibres from the contralateral eye combined with those in the phylogenetically newer projection from the ipsilateral eye ?

We shall discuss the results of neurophysiological investigations of single neurones which receive an input from both eyes. More than 80 per cent of the units in area 17 of the cat's cortex can be activated by a linear target (a bright slit, black bar or black–white edge) presented to either eye[4,5]. We have recorded action potentials from them with tungsten-in-glass microelectrodes and plotted their receptive fields by moving visual images across a screen 114 cm from the eyes. Image quality was preserved by corneal contact lenses, 3 mm artificial pupils and correcting lenses. The cat was anaesthetized by artificial respiration with a nitrous oxide/oxygen mixture and was paralysed by intravenous infusion of gallamine triethiodide (Flaxedil) and *d*-tubocurarine. The latter procedure, along with mechanical fixation of the eyes to metal rings, kept the eyes very stable. The projections of the optic disks on the screen were periodically plotted to ensure that no eye movement occurred. Our methods have been described in detail elsewhere[5,6].

Eye Preference of Single Cortical Neurones

We confirmed Hubel and Wiesel's observation[4] that binocularly driven units are often more effectively activated by a stimulus to one of the eyes than by a stimulus to the other, and that the contralateral eye is more often dominant. Fig. 1 illustrates responses from a unit that would fall into Hubel and Wiesel's eye-dominance group 2 and the histogram of Fig. 2 shows the distribution of eye-dominance among 228 cortical neurones from eighteen cats. We have excluded from the analysis 28 monocular units that were recorded in the white matter under the cortex. They had the fast action potential waveforms typical of nerve fibres and the receptive field properties of lateral geniculate cells[7]. We presume that they were axons in the optic radiation. We have also ignored a number of cortical units that were lost before receptive fields of both eyes were thoroughly explored. The eye-dominance groups of Hubel and Wiesel are explained in the legend to Fig. 2 and it is clear that almost twice as many cells are dominated contralaterally as are ipsilaterally.

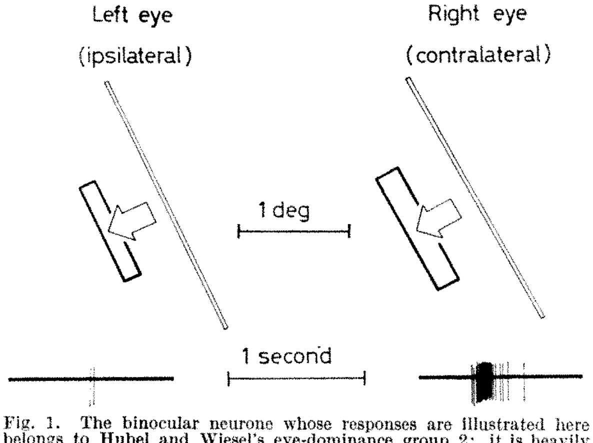

Fig. 1. The binocular neurone whose responses are illustrated here belongs to Hubel and Wiesel's eye-dominance group 2: it is heavily dominated by the input from the contralateral eye. The receptive fields for the left and right eyes are shown as rectangles on the left and right, respectively. Below each field is an oscilloscope record of the action potentials typically evoked from the neurone by a single, slow sweep of a thin bright slit across the receptive field in that eye. Clearly the unit is far more strongly activated by a stimulus to the right (contralateral) eye than by one to the left.

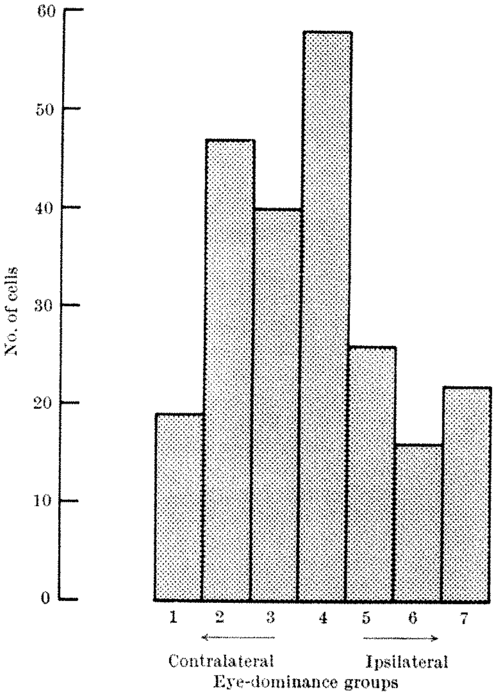

Fig. 2. This histogram shows the distribution of eye-dominance amongst 228 binocular cortical neurones. The group classification is as follows. Group 1: the neurone can only be influenced directly through the contralateral eye; 2: the contralateral eye is much more effective than the ipsilateral; 3: the contralateral eye is slightly more effective than the ipsilateral; 4: both eyes are equally effective; 5: the ipsilateral eye is slightly more effective than the contralateral; 6: the ipsilateral eye is much more effective than the contralateral; 7: the neurone can only be influenced directly through the ipsilateral eye; 106 of these units were therefore contralaterally dominated and 64 ipsilaterally dominated.

Each hemisphere, then, receives a somewhat greater excitatory input from the opposite eye than from the ipsilateral retina. It is noteworthy that the group classification of eye-dominance caters mainly for excitatory influences. The proportion of monocular neurones is even smaller if more subtle inhibitory effects are included in the analysis[8].

Retinal Disparity and the Two Projections

An interesting property of the cat's binocular neurones is that they do not necessarily have their receptive fields on precisely corresponding points in the two retinae. The horizontal disparity of the receptive fields varies over several degrees from cell to cell[5,6,9]. In effect, the trigger feature of a binocular cortical unit is an orientated target placed at such a position in the visual field, and at such a distance from the eyes, that its image falls on the receptive field in both eyes: and the optimal distance differs from cell to cell.

We now have a little more information about the anatomical and perhaps the phylogenetic origin of these disparities.

The first hint comes from Nikara, Bishop and Pettigrew's observation[9] that, for any small recording site in the cortex, the receptive fields tend to cover a wider area of retina in the ipsilateral eye than in the contralateral. We also noticed this during our experiments with H. B. Barlow[5] and decided to examine the point in more detail.

In each cat we made one or more penetrations into a tiny craniotomy which only exposed 3 or 4 mm^2 of cortical surface. We plotted the receptive fields of each binocular unit separately in the two eyes. They were invariably separated by a few inches on the screen because we had manipulated the eyes to make the visual axes divergent. We satisfied ourselves that if an image of the appropriate orientation was projected approximately on to the centres of the two fields and they were simultaneously moved back

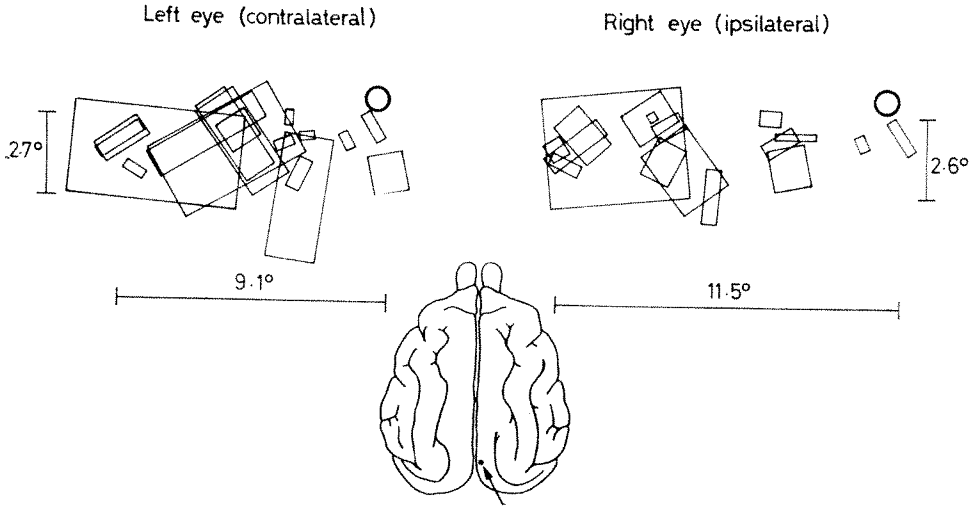

Fig. 3. Five penetrations were made, close together, into area 17 of cat 11 at the point shown on the sketch of the brain. All the reliably plotted receptive fields of the binocular neurones in the penetrations are shown above, those on the left for the left eye and on the right for the right eye. The arrays of fields have been rotated slightly to correct for twisting of the eyes during the experimental preparation. Near each array a circle marks the approximate position of the area centralis for that eye. Because the electrode was in the right hemisphere, the left eye is contralateral, and the receptive fields in that eye are less widely scattered horizontally than in the right eye.

and forth across the fields, the unit gave a facilitated binocular response[5,10].

We took photographs of the slit-like entrance pupils in the unanaesthetized cat and again after all the preparation. So, in spite of the slight twisting inevitably introduced by suturing the eyes to metal rings, we knew the true horizontal and vertical on the screen for each eye. We were therefore able to measure the horizontal and vertical dimensions of the patch of retina covered in the two eyes by the receptive fields.

Fig. 3 shows the results for one cat. In this case, five penetrations were made in the same region of area 17 in the right hemisphere, shown in the sketch of the brain. The receptive fields for all the binocular neurones are illustrated as rectangles: the array on the left is for the left eye and that on the right for the right eye. (This kind of receptive field plot has been called a minimum response field, or simply a response field, and the method and reliability of plotting have already been described[5,6,9].) The arrays have been rotated to correct for slight torsion in the two eyes. The circle near each set of fields marks the approximate projection of the area centralis in each eye. Clearly, for these seventeen binocular neurones the receptive fields are more widely scattered over the retina of the ipsilateral (right) eye than they are over the contralateral. In fact, the centres of the fields cover 11·5° horizontally and 2·6° vertically in the right eye, 9·1° horizontally and 2·7° vertically in the left.

Usually the horizontal spread of receptive field centres was a few degrees greater in the ipsilateral eye than in the contralateral, though there was no consistent difference in the vertical scatters. For some penetrations, particularly in the representation of the peripheral visual field, which is greatly compressed in its cortical map[4], the receptive fields from units in a small cortical region covered a large retinal area. Even in those cases the spread was usually a few degrees wider on the ipsilateral retina.

Figs. 4 and 5 analyse the results for 138 reliably plotted binocular neurones from fifteen craniotomies in twelve cats. The horizontal and vertical separations of the most extreme receptive field centres in every sample were measured, as in Fig. 3, and each point on the graph of Fig. 4 plots the spread in the ipsilateral eye against that in the contralateral, for one craniotomy. Solid circles show the horizontal spread, open circles the vertical. The continuous line with a slope of 1 is the expected relationship if the area of retina covered by the fields is identical in the two eyes. Clearly in only two cases was the horizontal range of receptive fields a little greater in the contralateral eye than in the ipsilateral. This is significantly different from a chance discrepancy (P = 0·008 : two-tailed binomial test).

The interrupted lines in Fig. 4 are the best fitting (least squares) straight lines through the solid and open circles. The line for the vertical spread is close to the continuous line but that through the horizontal data points is displaced upwards by about 2°.

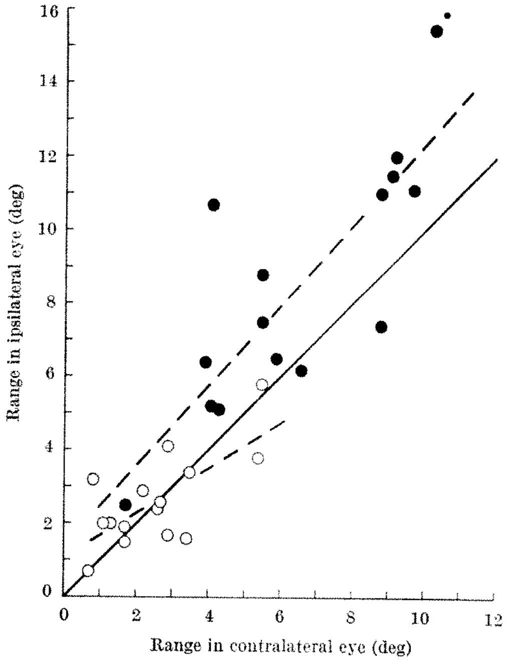

Fig. 4. Each point on this graph represents the angular separation of the centres of the most extreme receptive fields for the binocular units recorded in a single craniotomy. The smallest sample had four cells, the largest had twenty-one. The solid circles are for the horizontal spread of receptive field centres, and the open circles show the vertical spread. The range on the ipsilateral retina is plotted against that on the contralateral, for each sample. If the spread was always the same in the two eyes, all the points should lie along the solid line with a slope of 1. If the spread is greater in the ipsilateral eye the point will lie above this line. In these fifteen samples the horizontal scatter was greater in the ipsilateral eye for thirteen, but the vertical scatter for only seven. The upper interrupted line is the regression line through the solid circles and the lower one is that for the open circles.

Fig. 5 shows that the inequality in the horizontal range of receptive fields for the two eyes entails a genuine difference in scatter, and is not simply the result of one or two greatly misplaced fields on the ipsilateral retina. For in this second graph we have plotted not merely the separations of the extreme receptive fields in the samples, but the standard deviations of the distributions of position for all the receptive fields in each sample. Again, the scatter in the ipsilateral eye is plotted against that in the contralateral, and the solid and open circles refer to the standard deviations of the horizontal positions (angles of azimuth) and vertical positions (angles of elevation), respectively, of the centres of the receptive fields. See how this method confirms the fact that the fields are horizontally more broadly scattered across the ipsilateral retina, for twelve of the fifteen solid circles lie above the line with a slope of 1 ($P = 0{\cdot}036$: two-tailed binomial test). The vertical dispersion is, however, very similar in the two eyes: seven of the open circles are below the line and eight above.

We conclude from our experiments that the retinotopic mapping of the ipsilateral eye on the cortex is less precisely laid down than that of the contralateral eye. Indeed, it seems to be the apparent lack of anatomical specificity in the ipsilateral input which creates the range of horizontal disparities. Imagine a group of binocular cells in a small cortical region. The fibres arriving at this part of the cortex from the opposite eye represent a fairly well defined area of retina, but the phylogenetically younger input from the same side is, somehow, not so precisely localized. The anatomical diffusion in the ipsilateral retinotopology would, then, automatically lead to the formation of binocular neurones connected to a variety of points in the ipsilateral eye for each spot in the contralateral.

In the newborn kitten the vertical spread of receptive fields might also be greater in the ipsilateral eye and hence the range of vertical disparity might be as large as that of horizontal. Binocular cells representing large vertical disparities would almost never be simultaneously stimulated through both eyes in normal viewing conditions and, through lack of use, they might lose one or both inputs[11] and become functionless. Thus, in time, the anisotropy of horizontal and vertical disparity would appear.

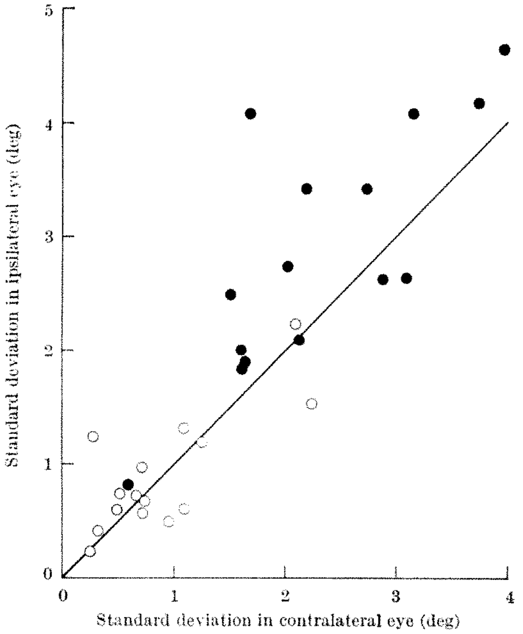

Fig. 5. The scatter on the two retinae for the samples of binocular units analysed in Fig. 4 is treated rather differently in this graph. The horizontal and vertical positions of the centre of every receptive field in the sample were measured, and each point plots the standard deviation of the distribution of locations in the ipsilateral eye against that in the contralateral eye for all the units in a single sample. Solid circles represent the horizontal scatter and open circles the vertical. The continuous line again has a slope of 1, the expected relationship if the dispersion were identical in the two eyes.

Binocular Nature of Cortical Columns

Another clue to how binocular messages combine comes from Blakemore[12], who investigated the organization of binocular neurones within the columns of the visual cortex. Hubel and Wiesel[4] have described how these blocks or sheets of cortical tissue contain cells that all have the same optimum target orientation, and it turns out that these orientation columns fall into two classes according to the arrangement of their binocular cells. Some of them, termed depth columns, have almost identical arrays of receptive fields in the two eyes and consequently the disparity is virtually the same for all units in the column. The column as a whole is looking at objects of some orientation at a certain distance from the eyes.

On the other hand, there are certain so-called direction columns in which all the receptive fields are superimposed on the retina contralateral to the hemisphere containing the column, but are horizontally scattered in the ipsilateral eye. The disparity therefore varies enormously from cell to cell, and the column as a whole is viewing objects of one orientation falling along a single oculocentric visual direction based on the contralateral eye.

If certain higher-order neurones in each column receive messages from many of the lower-order cells, as suggested by Hubel and Wiesel[4], then such a "complex" cell would, in a depth column, represent an object at one distance from the eyes but over some range of position in the visual field. In a direction column the "complex" unit would signal the oculocentric position of an object in the contralateral eye, regardless of its depth in space.

In these direction columns, then, the topographic representation of the contralateral eye is more exactly specified than that of the ipsilateral input, just as in any patch of cortical tissue, containing many columns.

A picture thus emerges of the visual cortex of the cat dominated by the traditional crossed visual input. The intruding optic fibres from the eye on the same side are usually less effective in exciting the neurones and not so precisely projected on the cortex. But it is this very element of difference in the two projections which creates the disparities of binocular cells and gives them their ability to encode the distances of objects in space. A system has developed for using the disparity information and the neurones have been organized into functional columns. Within many of these columns it is still the contralateral eye which dominates and determines the arrangement.

It is therefore the dispersion of the phylogenetically younger ipsilateral input which supplies the evolutionary advantage of frontal eyes, namely, the cue for discriminating the relative distances of objects from the eyes.

We thank Professor H. B. Barlow for help and for financial support from a US Public Health Service grant. C. B. was sponsored by a research fellowship from Fight For Sight, Inc., New York.

Low Mode Coherent Synchrotron Radiation and Pulsar Phenomena

by
BERNARD J. EASTLUND
Division of Research,
US Atomic Energy Commission

Information on the properties and distributions of the charges responsible for pulsar emission can be deduced from an appraisal of the coherent synchrotron radiation from an oblique rotator model.

THIS article is an extension of my original calculations on the oblique rotator–coherent synchrotron radiation model for pulsar r.f. emission[1,2] and a comparison with observations. In this model the knife-like angular pattern of coherent synchrotron radiation is converted into a time dependent pulse by rotation of the star (Fig. 1).

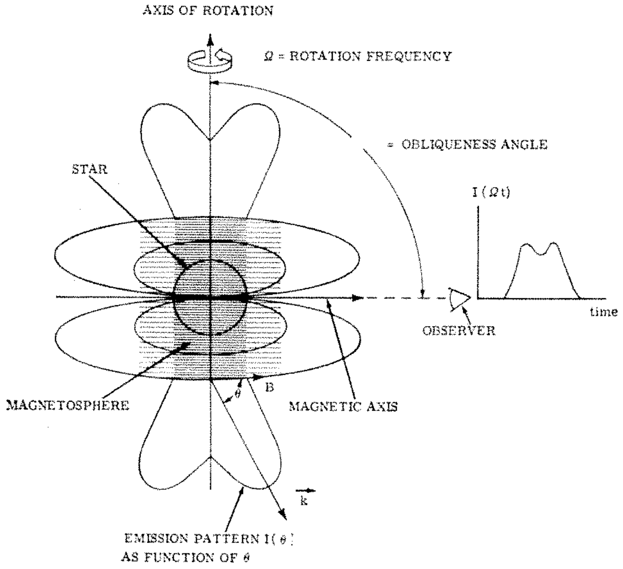

Fig. 1. The oblique rotator–coherent synchrotron radiation model for pulsar emission.

The comparison with observations determines (*a*) a lower limit for the average energy of the radiating charges ($E > 100$ MeV), (*b*) the average magnetic field in the radiation region (10–100 G), and (*c*) the particle Larmor radius (on the order of kilometres). A refined model is then found to lead to an explanation of (*a*) the fine structure, (*b*) repetitive phenomena on a kilocycle time scale, (*c*) the absence of even–odd pulse effects for obliqueness angles in which two pulses should be emitted per rotation, and (*d*) the appearance of a double peak on averaged signals when single pulses appear on a pulse to pulse basis.

The Calculation

The synchrotron radiation intensity as a function of mode, *m*, and angle θ (the angle perpendicular to the plane of the particle orbit) was shown in ref. 1 to be

$$P_m = \frac{e^2 m^2 \omega_L^2}{8\pi\varepsilon_0 c}\left[\left(\frac{\cos\theta - \beta_{\parallel}}{\sin\theta}\right)^2 \mathrm{J}_m^2\,(m\beta_{\perp}\sin\theta) + \beta_{\perp}^2\,\mathrm{J}_m'^2\,(m\beta_{\perp}\sin\theta)\right] \quad (1)$$

where ω_L is the Larmor angular frequency, $\beta_{\parallel} = v_{\parallel}/c$, and $\beta_{\perp} = v_{\perp}/c$. The polarization of this radiation, in cartesian coordinates, was shown to be

$$E_x = -A\,\frac{\cos\theta}{\sin\theta}\,(\cos\theta - \beta_{\parallel})\,\mathrm{J}_m(x)$$

$$E_y = -A\,i\beta_{\perp}\,\frac{\mathrm{d}\,\mathrm{J}_m(x)}{\mathrm{d}x} \quad (2)$$

$$E_z = A\,(\cos\theta - \beta_{\parallel})\,\mathrm{J}_m(x)$$

where $x = m\beta_{\perp}\sin\theta$ and $A = (e^2\omega_L^2 m^2/8\pi^2\varepsilon_0 c)^{1/2}$.

The present calculations evaluate the equations up to mode number 950 (the limit of the Bessel function subroutine). Transformation from angular dependence to time dependence was made as follows

$$P_m(\theta) = P_m\left(\frac{2\pi}{\tau}\,t\right) \quad (3)$$

where τ is the pulsar repetition rate. Such a transformation corresponds to the assumption that the repetition rate is equal to the rotation period. Twice the experimental period is also used in calculations for Table 1. It is assumed that $\beta_{\parallel} = 0$. (Further work is in progress to study the effect of $\beta_{\parallel} \neq 0$.)

Table 1. PARAMETERS FOR TWO PULSARS

	Case	Period (s)	r.f. measured (MHz)	Mode No. calculated	f_0 (kHz)	B (G)	r_L (m)
CP 1133	B	1·187	111·5	710	162	11·5	290
CP 1133	A	2·376	111·5	4,800	24	1·72	1,980
NP 0527	B	3·745	320	135	2,360	165	20
NP 0527	A	7·490	320	880	364	25·8	132

Pulse shapes as a function of mode number are presented in Figs. 2 and 3 for pulsar CP 1133 ($\tau = 1{\cdot}187$ s). Fig. 2 is a set of pulses calculated for a charged particle energy of 5 MeV ($\gamma = ||$ where $\gamma = (1-\beta_{\perp}^2)^{-1/2}$). Note the transition from a double peak at low mode numbers to a single peak at high mode numbers. Pulse shapes for an energy of 100 MeV are plotted in Fig. 3 ($\gamma \approx 200$). The double pulse persists up to the limit of the calculations.

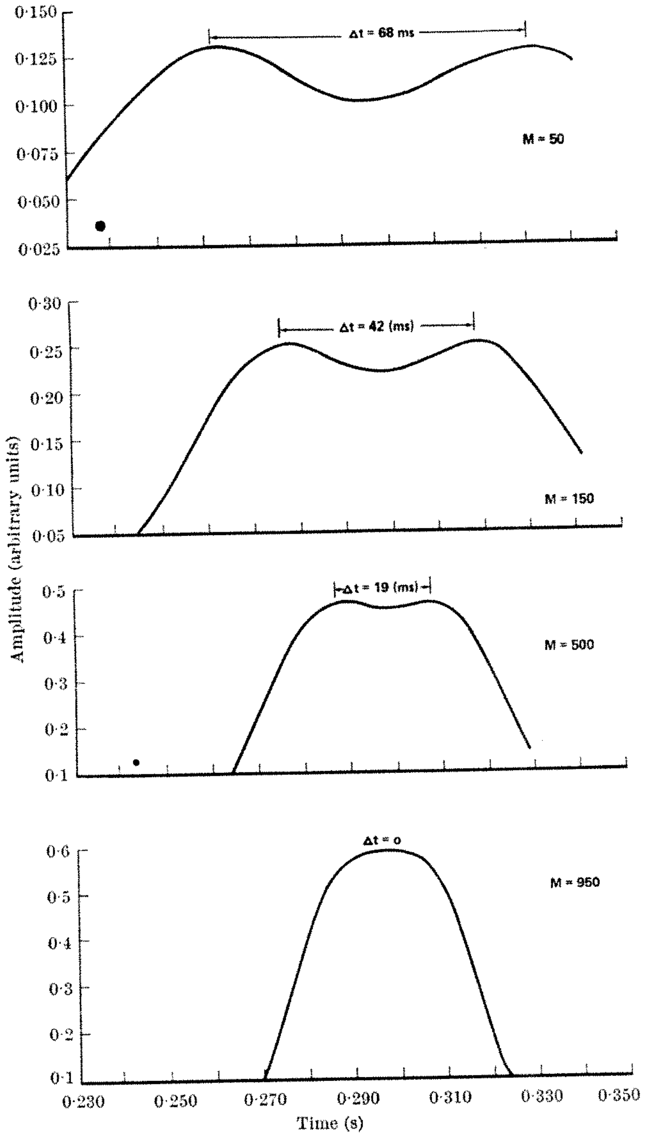

Fig. 2. Predicted pulse shapes (CP 1133) as a function of synchrotron mode number with rotation period, τ, equal to 1·187 s. Charged particle energy is 5 MeV.

The frequency dependence (synchrotron mode number) of the peak to peak pulse widths is presented in Fig. 4 with charged particle energy as a parameter. As the particle energy increases, the transition from double to single peaks is seen to move to higher mode numbers. When the particle energy becomes greater than 100 MeV the frequency dependence approaches a constant slope. Thus one might expect the calculated slope to be found in more than one pulsar (as indeed is the case).

This frequency behaviour of pulse shapes can easily explain why some pulsars exhibit frequency dependent pulse widths and others do not. Clark and Smith, who have used a coherent synchrotron radiation model, use the standard approximation for synchrotron angular emission to relate pulse widths to the energy of the radiating particles[3]. The standard expression is[4]

$$\gamma \cong \frac{1}{\Delta\theta} \tag{4}$$

($\Delta\theta$ represents one-half the total angle). This expression can be derived from equation (1) for large γ and values of m greater than γ^3. The present calculations are for mode numbers less than 1,000 and show both the width and the shape of the polar diagram to be frequency dependent. Note that when the transition from a double to a single peak occurs (for high mode numbers) the pulse width does approach that predicted by equation (4). For example, at 5 MeV, equation (4) predicts a pulse width of 34 ms for CP 1133. At mode 950 (see Fig. 2) the single peak is 40 ms wide at its half power point. The width of the single peak is found to be independent of mode number for modes greater than 800 at 5 MeV.

The curves in Fig. 4 can be easily transformed for comparison with other pulsars by the following expression:

$$\Delta t_2 = \tau_2 \, \Delta t_1 / 1{\cdot}187 \tag{5}$$

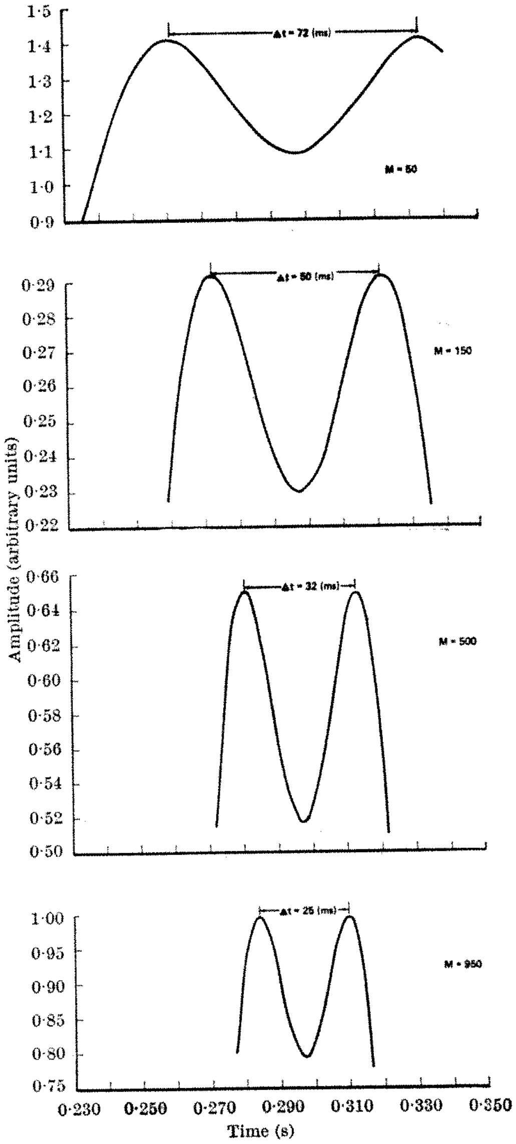

Fig. 3. ulse shapes as a function of mode number, with $\tau = 1{\cdot}187$ s, for particle energy of 100 MeV.

where Δt_1 = peak to peak time separation in Fig. 4, τ_2 = period of pulsar to be studied, and Δt_2 = peak to peak time separation of the new pulsar.

Representative plots of predicted polarization for CP 1133 are presented in Figs. 5 and 6. Fig. 5 is a plot of E_z, which could represent the circular component of a received signal. It is found that, for a given mode number, the separation between the peaks in polarization is greater than the peak to peak separation of the signal amplitude. The linear, E_x and E_y components are plotted in Fig. 6. Measurements of polarization for CP 1133 and NP 0527 have not been reported. Clark and Smith[3] have measured the polarization of signals from CP 0238 and have found effects similar to those shown in Figs. 5 and 6.

Comparison with Experiment

Average pulse shapes as a function of frequency have been reported by Craft and Comella[5] for CP 1133 and by Zeissig and Richards[6] for NP 0527. Ekers and Moffet[7] have reported both individual pulse and average data for CP 1133. The calculated frequency dependence of peak to peak time separation is plotted in Fig. 4. The data for CP 1133 and NP 0527 are found to have a constant slope; thus the data were compared with the calculations for electron energy $E > 100$ MeV.

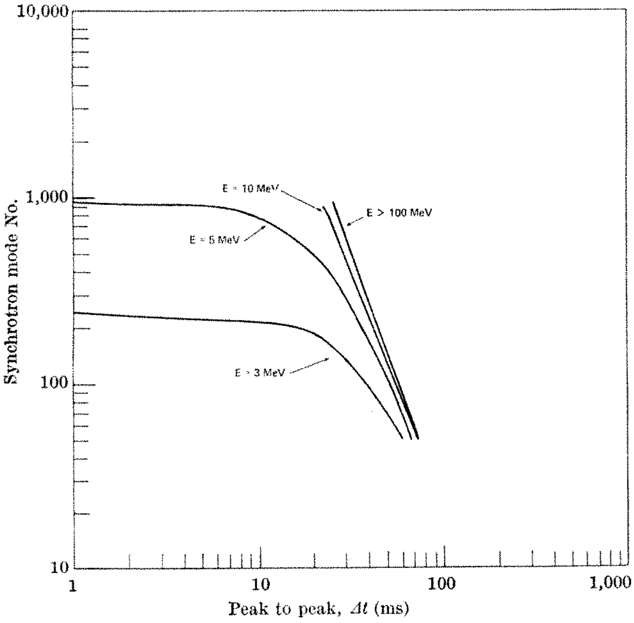

Fig. 4. Peak to peak pulse separation, Δt (for double peaked pulses), as a function of synchrotron mode number with charged particle energy as a parameter ($\tau = 1{\cdot}187$ s). The particles were assumed to be electrons. If protons are to be considered, protons with a value of γ that corresponds to the equivalent electron γ should be chosen.

The data were normalized in mode number by (*a*) choosing the cleanest average pulse with the best signal to noise ratio and (*b*) setting the observed frequency of that pulse equal to the mode number that corresponds theoretically to the measured pulse width.

Pulsar CP 1133 is compared with the calculations in Fig. 7. The data between 40·12 MHz and 430 MHz are average pulse data from Craft and Comella[5]. The point at 2,295 MHz is an individual pulse from Ekers and Moffet[7]. The computations were only performed up to mode 950. Fig. 4, however, seems to indicate that the slope of the $E > 100$ MeV line is constant until the double peak behaviour ceases (see the 5 MeV curve in Fig. 4). Thus the solid line in Fig. 7 has been extended by a dashed line to approximate the behaviour of the Δt dependence for energetic particles at mode number > 950. It is interesting to note that both individual pulse data and average pulse data agree well with the calculations over a factor of 50 in frequency. (Smith[8] has determined that individual pulses from pulsar CP 0328 do not show frequency dependent pulse widths over a frequency range from 151 to 1,420 MHz. The individual and average pulse data from CP 1133 indicate that this is not the case for all pulsars. The model proposed by Smith may be applicable to CP 0328 but does not seem to apply in the case of CP 1133.) The actual average pulse shape for the received signal at 111·5 MHz is compared with the predicted pulse shape for mode 700 in Fig. 8.

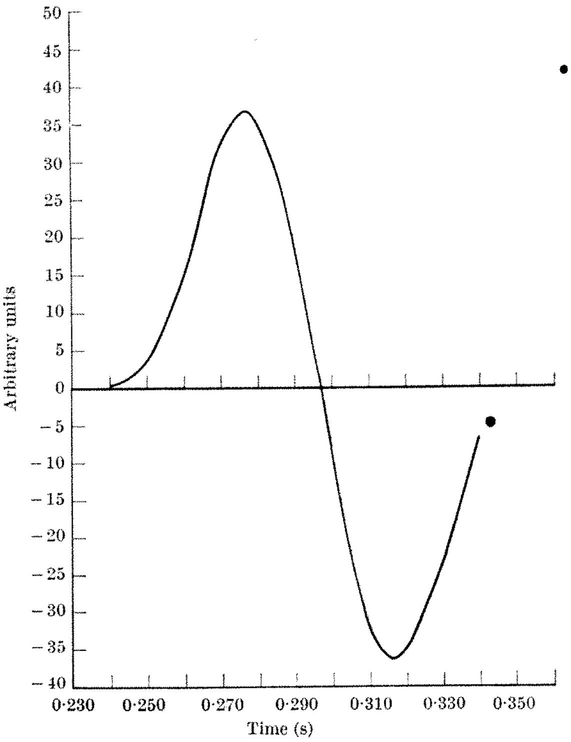

Fig. 5. The circular component (E_z in equation (2)) of the predicted polarization at 96 MHz for CP 1133.

Finally, the average pulse data from NP 0527 are compared with the calculations in Fig. 9. As indicated by theory, the slope indicated for frequency pulse widths of particles with $E > 100$ MeV seems to be a phenomenon present in more than one pulsar.

Charge Orbital Parameters

Further information concerning the properties of the radiating charges and their orbital characteristics can be

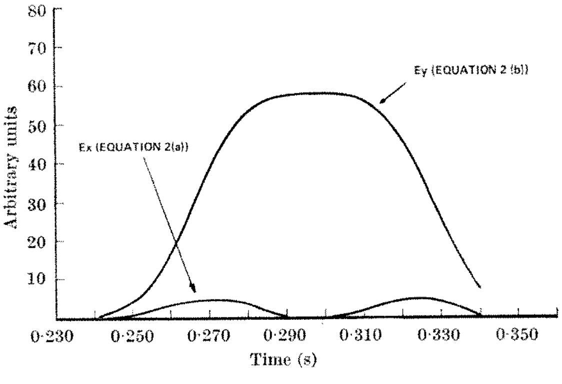

Fig. 6. The linear components (E_x and E_y in equation (2)) of the predicted polarization at 96 MHz for CP 1133.

deduced from the data. These properties are (*a*) the average particle energy, (*b*) the fundamental synchrotron frequency, (*c*) the average magnetic field in the radiating region, and (*d*) the Larmor radius of the particle orbits. The sign of the charges (electrons, protons or higher Z atoms) cannot be deduced from the analysis as the theoretical emission patterns are independent of the charge.

The comparison of pulse width versus frequency indicates that the average electron energy is greater than 100 MeV ($\gamma \simeq 200$). The corresponding proton energy would be greater than $1 \cdot 8 \times 10^{11}$ eV. If a pulsar can be found in which the transition from a double peak to a single peak can be measured, then the actual particle energy could be determined.

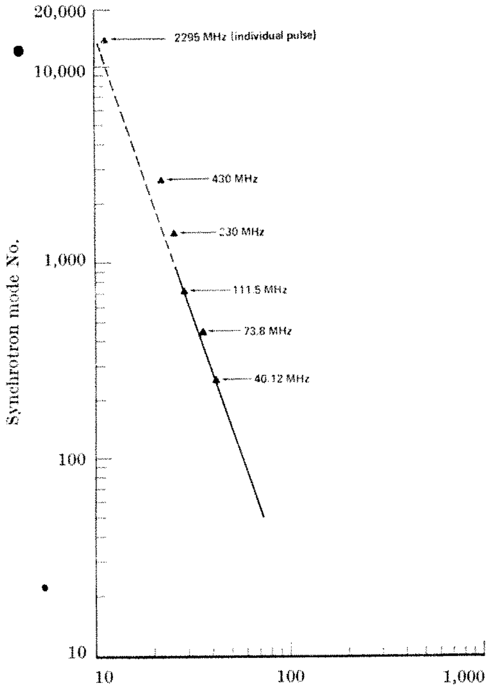

Fig. 7. Frequency dependent pulse width data for CP 1133 (▲) compared with the calculations. The normalizing mode number was found by matching the theoretical pulse width value with the measured value at 111·5 MHz. ——, Equation (1), $E > 100$ MeV.

The normalization procedure that related mode number to measured frequency also gives the fundamental Larmor frequency, f_0, of the radiating charges. This fundamental is equal to the measured frequency divided by its corresponding mode number. The equation for f_0 is

$$f_0 = \frac{eB}{2\pi\gamma m_0 c} \tag{6}$$

For large values of γ, the Larmor radius, r_{L}, is related to f_0 as follows

$$f_0 = \frac{c}{r_{\mathrm{L}}} \tag{7}$$

Table 1 shows the values of f_0, B and r_{L} obtained in this manner for pulsars CP 1133 and NP 0527. One pulse per rotation period was assumed in the calculations for Figs. 7 and 8 (that is, the measured period was used in equation (3)). As two pulses per period are also possible (case A of ref. 1), the parameters f_0, B and r_{L} were also determined for $\tau_2 = 2\tau$ and plotted in Table 1 for each pulsar.

A Refined Model

The large Larmor orbits deduced here are of the order of kilometres and are thus comparable with the size of neutron stars[9]. This suggests to me that the bunches of high energy ($\gamma > 200$) charged particles responsible for the r.f. pulse may actually be orbiting the magnetosphere. The r.f. emission might thus originate from a train of charge bunches with each bunch having dimensions of the order of the largest wavelength of the emitted radiation (Fig. 10). The observed average pulse shape (Fig. 8) would then represent the envelope of a succession of very sharp r.f. bursts.

The following should be considered: (1) The means of production of charges with values of $\gamma > 200$. (2) The means by which the charges could enter an orbit encircling the magnetosphere. (3) Possible mechanism for bunching of orbital relativistic charged particles.

Several mechanisms have been proposed for the production of ultrarelativistic charged particles at both the surface of a rotating neutron star with a magnetosphere (unpublished work of Goldreich) and in the near-field region of such a spinning object[10]. Only a small fraction of such particles would need to be trapped to account for the r.f. emission. (Gunn and Ostriker show that the r.f. pulse itself represents only 10^{-7} of the total magnetic dipole energy that can be released by a neutron star with an oblique magnetic field[10].)

The means by which such particles could orbit the star is not clear, but stable or quasi-stable orbits would certainly exist[11], and either direct particle collisions or instability mechanisms could deflect particles into such orbits.

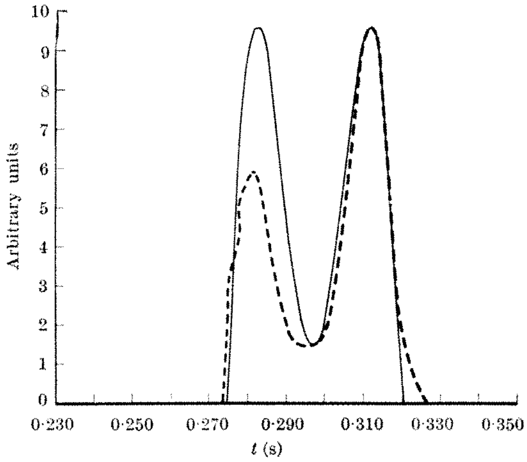

Fig. 8. Comparison of the measured average pulse shape at 111·5 MHz with synchrotron mode number 700. – – –, Data (CP 1133); ——, equation (1).

Once in orbit, relativistic charges (electron or proton) would be subject to the negative mass instability[12]. This instability is prevalent in circulating charged particle beams in accelerators and storage rings. According to ref. 12, "the instability can arise whenever the frequency of rotation of the particles is a decreasing function of energy—as, for example, with a relativistic electron beam in a uniform magnetic guide field. In such cases, an accelerating force on the particles results in a decrease in the angular velocity, so it is not hard to see that electrostatic space-charge forces arising from some small perturbation in the beam charge density would then result in motion towards a region of increased density, thus leading to a progressive enhancement in the beam bunching". This instability has been observed in the Astron device at the Lawrence Radiation Laboratory[13]. A ring of 3·8 MeV electrons at current levels of the order of 100 A is observed to bunch azimuthally. Theoretically predicted growth rates were found to agree well with observation.

The negative mass instability is an example of a natural means by which a sufficient number of electrons can be aligned in phase and in space to produce coherent synchrotron radiation. Various factors can influence the size of the bunch and the length of time over which a given bunch or bunches can maintain alignment. Two mechanisms which destroy the alignment come to mind. First, the bunch can lose energy via the synchrotron emission and thus be more susceptible to space charge spreadings. Second, the synchrotron emission could result in an energy spread of particles in the bunch, and violate conditions necessary for the instability.

The growth of bunches and their decay can lead to a wide variety of pulse shapes, depending on the time scales involved. For example, if the decay rate is slow compared with the pulse width, one could expect to see a complete double pulse for some pulses as is observed in CP 1133 (ref. 7).

If there are no bunches sufficiently aligned to produce coherence, then pulses would not be observed. If the decay rate is shorter than a pulse width, then only a portion of a double pulse would be observed. All such behaviour is denoted in Fig. 3 of ref. 7.

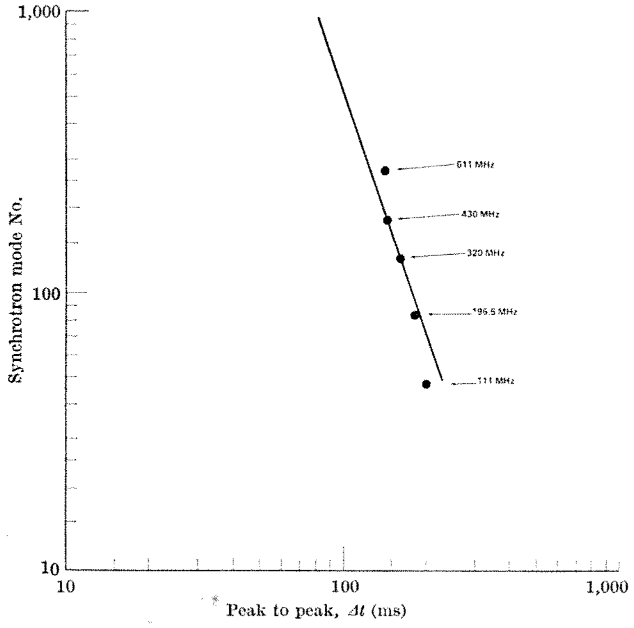

Fig. 9. Frequency dependent pulse width data for NP 0527 (●) compared with the calculations[6]. The normalizing frequency was chosen at 320 MHz. ——, Equation (1), $E > 100$ MeV.

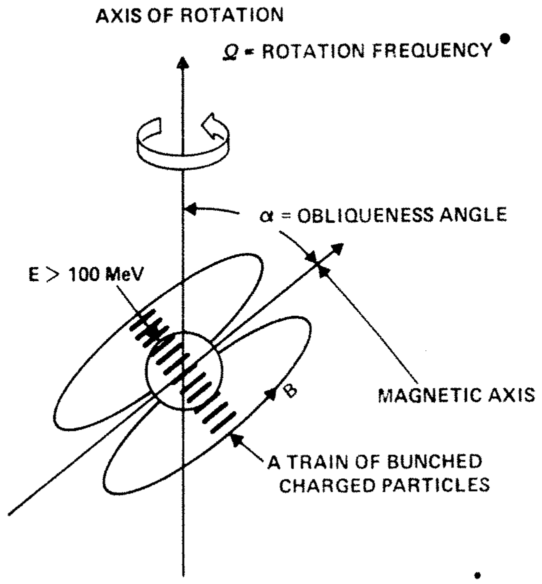
Thus, individual pulses can have an erratic behaviour, sometimes appearing as single peaks or double peaks, while the average pulses have a shape more characteristic of the calculated synchrotron pattern. The refined model suggested here can lead to an explanation of some of the other rather erratic pulse to pulse behaviour that has been observed. Fine structure (sharp microsecond pulses within the main envelope)[14] could be generated by emission from many individual bunches during the time in which the synchrotron emission pattern is aligned with the observer. For example, at a value of f_0 of 162 kHz one bunch would orbit the magnetosphere 8,100 times during one 50 ms r.f. burst (CP 1133). One might expect to observe periodic kilocycle effects in the fine structure that would result from the growth and decay of individual bunches.

The growth and decay times of individual bunches of charged particles could be longer than the time between pulses. If so, then the rapid orbiting behaviour described could account for the absence of pronounced even–odd pulse effects for obliqueness angles in which two pulses are emitted per rotation of the source star. This can happen because the same coherently emitting bunches would be orbiting the star during both pulses. As long as the bunch size remains the same, the amplitude of the r.f. bursts should be approximately equal. (To avoid confusion, it should be noted that while the phenomenon resulting in the bunching is referred to as an "instability" its effect is to align charged particles in bunches of finite dimensions for finite time periods, that is, times much greater than the cyclotron period.)



AXIS OF ROTATION

MAGNETIC AXIS
B
A TRAIN OF BUNCHED CHARGED PARTICLES

Fig. 10. A refined pulsar model. One or more (growing or decaying) charged particle bunches are hypothesized to be in orbits encircling the neutron star's magnetosphere.

If the model is realistic, and if a negative mass instability is present, then the mass of the charged particle could be determined from the growth rates of the instability. This could allow direct detection of cosmic rays by study of their emission patterns. At energies as great as those deduced from the data, optical, X-ray and possibly even gamma ray emission are possible. (The r.f. power spectrum would still be similar to that described in Fig. 2 of ref. 1, however.)

Extension of the calculations to (*a*) higher mode numbers, (*b*) finite $\beta_{\parallel}$ and (*c*) arbitrary obliqueness angles[15] is under way.

LETTERS TO THE EDITOR

PHYSICAL SCIENCES

High Resolution Observations of Solar Microwave Bursts

At Toyokawa Observatory we have been mapping the brightness and polarization distribution across the Sun at intervals of 10 s by a quick scanning system installed at the 8 cm radio interferometer since the end of August 1968 (ref. 1). The base line of the 32 element adding interferometer is 213·28 m or 2,666 wavelengths, which corresponds to a half-power beam width of 1·1 min of arc. This letter describes two examples of bursts with double structure which have been observed during the past eight months.

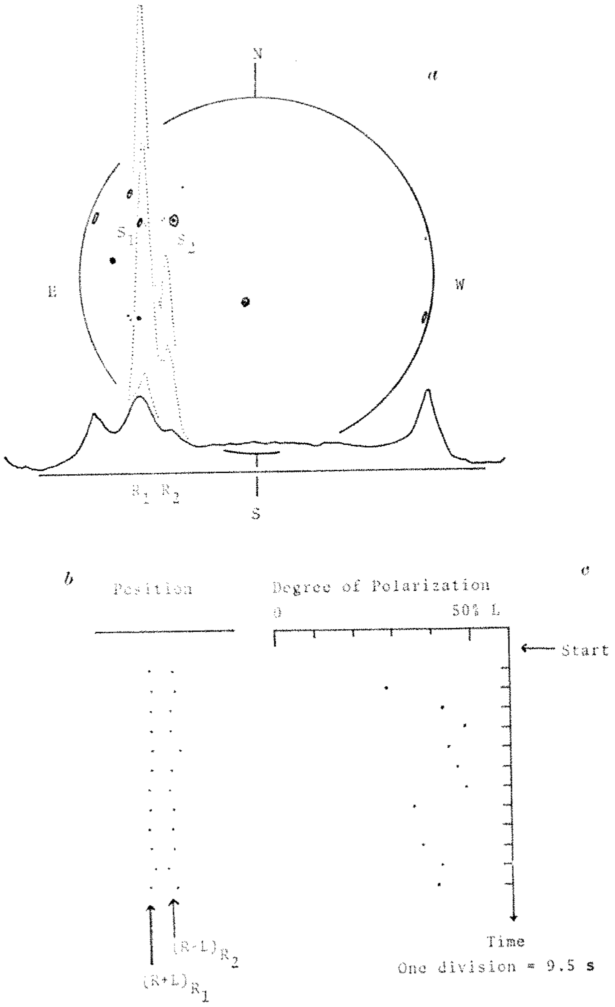

Fig. 1. *a*, One-dimensional brightness distribution at 3·75 GHz and the sunspot sketch (Mitaka) on January 18, 1969. R_1 and R_2 represent the burst sources and S_1 and S_2 are the corresponding sunspots respectively. *b*, The time variation of the position of sources R_1 on the $(R+L)$ channel and R_2 on the $(R-L)$ channel. *c*, The time variation of the degree of polarization of R_2.

‡ Greater than.

On January 18, 1969, at 0200.5 UT, an impulsive burst of the simple type was observed. Fig. 1*a* shows drift curves of the Sun before the burst (solid line) and at different stages of the burst (dotted lines) together with a sunspot sketch from Tokyo Astronomical Observatory (Mitaka). There were two radio sources, R_1 and R_2, with R_2 appearing about 10 s after R_1.

The results of single frequency observations and H_α solar flare patrols are summarized in Table 1. The position of R_1 may certainly be identified with that of the flare, but there are no detailed flare records for R_2, and all we can say is that it may be located at or near the sunspot S_2.

R_1 was unpolarized, but R_2 showed 40–50 per cent left-handed circular polarization (Fig. 1*c*). The positions of the sources R_1 and R_2 were stationary during the burst on the channel of the sum of left-handed (L) and right-handed (R) circular components. On the $(R-L)$ component channel, on the other hand, the source R_2 showed a definite movement of roughly 1 min of arc in 10 s near the maximum stage of activity (Fig. 1*b*). In our polarization measurements we do not observe all the Stokes parameters, so we cannot discriminate polarized components from randomly polarized components. It can be shown that the apparent motion of the source of the polarized component may have to be multiplied by the factor $2P/(1+P)$, where P denotes the degree of polarization. In this case the factor is 0·6. Then the motion of the radio source R_2 is estimated to have been 0·6 min of arc in 10 s, that is, $\sim 2{,}500$ km s^{-1}.

What is most striking about the January 18 event is the parallelism of the activities in both radio sources from just before the maximum and later on (Fig. 2). If our identification of the radio sources is correct, the distance between both sources is $\sim 1{\cdot}6\times10^5$ km. We conclude that the time delay of radioactivities in the two sources spaced by $\sim 1{\cdot}6\times10^5$ km was less than a few seconds.

From drift-scan observations at 9·4 GHz and of single frequency observations at 9·4, 3·75, 2 and 1 GHz it is possible to separate the activities in each source by the time delay of their start. The estimated polarization character of each source during the burst activity is shown in Table 2. Each source had an opposite sense of polarization and the sense of circular polarization reversed with frequency around 3·75 GHz for the source R_1 and between 2 and 1 GHz for the source R_2.

On December 24, 1968, weak and complex radioactivity started at 0154 UT and an impulsive burst of simple type

Table 2. POLARIZATION CHARACTER OF THE JANUARY 18 BURST

Frequency (MHz)	Radio sources R_1	Radio sources R_2
9400	R	~0
3750	~0	L
2000	L	L
1000	L	R
	● or ~0	R

occurred in succession. A composite picture of drift curves and a sunspot sketch similar to Fig. 1*a* is shown in Fig. 3*a*, where dotted lines and a broken line indicate brightness distributions of the sources at different phases of the burst activity. The associated flare was observed at Mitaka and is illustrated in Fig. 3*a* as F.

This event is quite similar to the January 18 event in that there were two radio sources R_1 and R_2 corresponding to a burst; that the source R_1 preceded the source R_2 by one drift curve, namely, by 10 s; and that the source R_1 was unpolarized whereas the source R_2 was left-handed circularly polarized.

In details, however, there were some differences. Neither source moved in the (R − L) channel or the (R + L) channel, and the radioactivity in both sources was not paralleled as in the sources of January 18, 1969. The enhancement rise time was definitely different in both sources (Fig. 4). The polarization of each source is shown in Table 3. At 2 and 1 GHz we cannot separate the components corresponding to each source by the polarimeter observations, as we have done in the case of the January 18 event. As Table 3 shows, the reversal with frequency is not clear in this case.

Frequency (MHz)	Radio sources R_1	R_2
9400	L	~0
3750	~0	L

The most interesting point with respect to the burst of December 24, 1968, is that, although there was a flare of importance 2F associated with the radio source R_1, none was observed for the burst source R_2. But we may suspect that the radio burst took place somewhere in the neighbourhood of the sunspot S_2 without any flare activity or even a subflare.

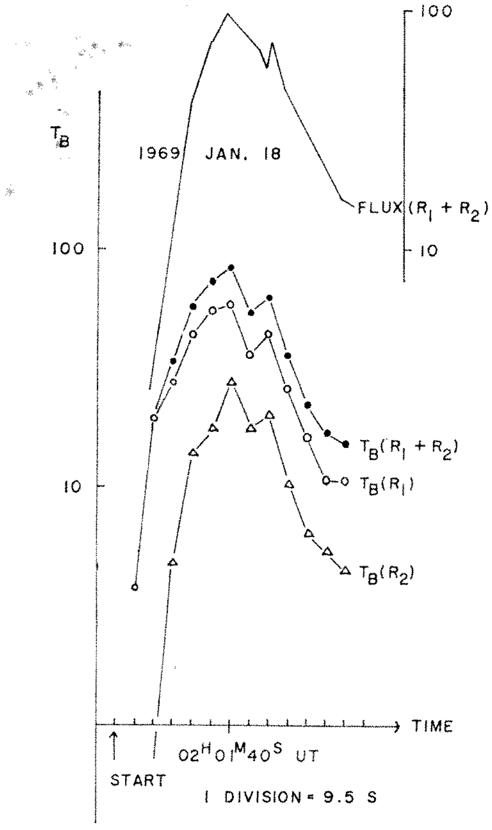

Fig. 2. From upper to lower; time variations of the flux density in units of 10^{-22} W m^{-2} Hz^{-1} with the scale on the right hand side, the sum of the brightnesses of both sources, the brightness of R_1, and the brightness of R_2 in arbitrary units.

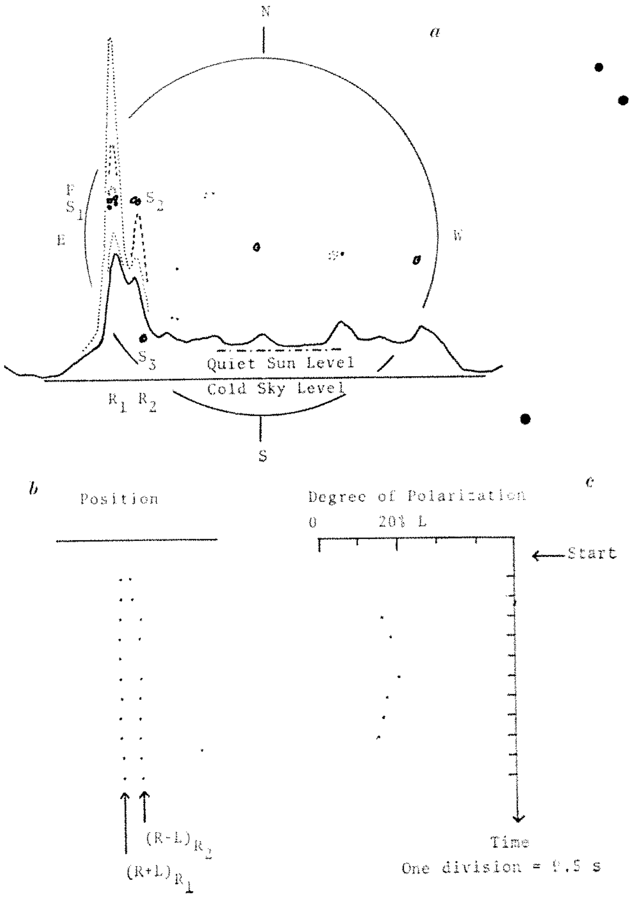

Fig. 3. *a*, One-dimensional brightness distribution of the Sun at 3·75 GHz and the sunspot sketch (Mitaka) on December 24, 1968. R_1 and R_2 represent the burst sources and S_1 and S_2 are the corresponding sunspots respectively. S_3 has nothing to do with the present activity. F is the flare associated with R_1. *b*, The time variation of the position of the sources R_1 on the (R + L) channel and R_2 on the (R − L) channel. *c*, The time variation of the degree of polarization of R_2.

The time delay of the start of radio enhancement observed clearly for two separated sources in both cases suggests a disturbance which triggered the microwave burst propagated from one source to another at $\sim 1{\cdot}5 \times 10^4$ km s^{-1}. But there is no known disturbance with such a velocity. Here we consider as possible mechanisms hydromagnetic shock waves and high energy particles.

If we take an electron density of 10^8 cm^{-3} and a magnetic field strength of 70 oersted for the active region, the Alfvén wave velocity may be $1{\cdot}5 \times 10^4$ km s^{-1}. Thus as in the case of Moreton wave phenomena it may be possible to consider triggering due to hydromagnetic waves[2,3].

In the case of high energy particles, it may be that high energy electrons radiating microwave emission, probably by magnetobremsstrahlung, in the first source, transferred to the second source and caused secondary emission. In this case, however, the emission mechanism suggested by Takakura and Kai[4], by which they tried to explain the spectrum and the duration of microwave bursts as due to the magnetobremsstrahlung by electrons with an energy of hundreds of keV, has to be extended to account for the rather slow propagation of electrons along the magnetic field lines between the radioactive centres.

We are not in a position to conclude which model is correct, but the difference of rise time for the burst of December 24 may not be accounted for easily by the particle model. On the other hand, the fact that there was only radioactivity in the region of R_2 for the event of December 24, and that there was a parallelism between both sources for the event of January 18, may be in

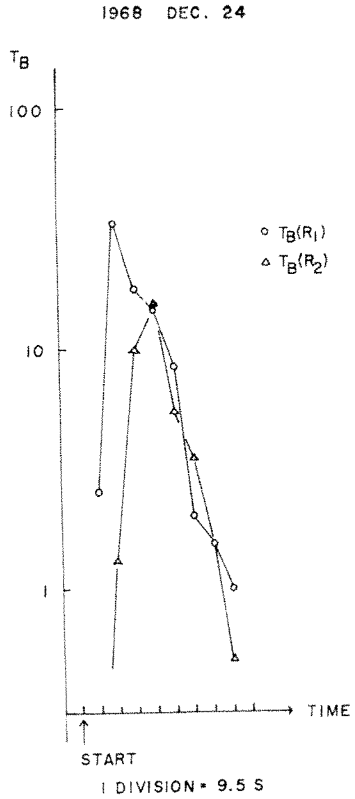

Fig. 4. Time variations of the brightness of the sources R_1 and R_2 in arbitrary units.

favour of the particle model, because they suggest radiation from common high energy electrons. We suggest as a working model that hydromagnetic shock waves accelerate electrons which emit the microwave radiation and heat the magnetic flux tubes between both sources, and that these hot flux tubes may become good channels for the propagation of high energy electrons.

The sense reversal of polarization with frequency was originally found by Kakinuma[5,6], and since then various theories have been proposed[5,7-11]. We have pointed out another possibility in which a bipolar source with opposite senses of polarity may give rise to a sense reversal if the sources have a different radio spectrum[12]. It is clear from Table 2, however, that both the propagation condition and the spectrum of each source took part in the observed polarization character of the January 18 burst. Thus the problem of the polarization characteristics of solar radio bursts due to the propagation condition is still unsolved.

There are several observations of motion of the sources of solar radio bursts[13,14] in which a polarization centre moved at the beginning of the second phase of an intense burst. We have inferred that this movement is caused by a motion of the magnetic field. But for movement as rapid as that observed during the impulsive burst on January 18, we have to consider the possibility of motion of the radiating centre as a whole.

We thank the Division of Solar Physics of Tokyo Astronomical Observatory for the optical data, and the staff of our laboratory for their help.

Pulsar Periods and Rapid Changes in the Terrestrial Rotation Rate: a Reply

Maran and Ögelman[1] have called attention to the influence on observed pulsar periods of a changing rotation period of the Earth. We think that their estimates are not entirely correct. They have not properly distinguished between the time rate of period change $\Delta P/P = \dot{P}$, and the uncertainty of a period determination $\delta P/P$. They give an estimate of the absolute uncertainty in the determination of the dimensionless quantity $\dot{P}$ and interpret this number as relative uncertainty for the period determination. (Note that $\Delta P/P$ is not uniquely defined. In ref. 2 it is a dimensionless quantity and equals $\dot{P}$, that is, the time derivate of the period, or the relative change of period per period. In ref. 3 it has, apparently, the dimension of a time and equals $P\dot{P}$, or the absolute change of period per period.)

It is necessary to distinguish between an absolute period change and a rate of period change. The basic observed quantity for any period determination is the pulse arrival time. If the length of a day changes by a fixed amount, then the apparent period during rising or setting time of the pulsar changes, due to a changed Doppler effect, by a fixed amount. A fixed period change has a linearly accumulating effect on the arrival times, and can therefore be measured with a precision that increases linearly with time. On the other hand, a continuous period change by a fixed rate which seems to be an intrinsic property of some pulsars has a linearly accumulating effect on the period, and can therefore be measured with a precision that increases with the square of time.

If one observes over a period which totals $m+1$ pulses the period is given by $P = T/m = (t(m+1) - t(1))/m$, where t is the arrival time. The uncertainty is $2\tau/m$, where τ is the accuracy in the timing of the first and the last pulse. τ contains a systematic part, τ_{sy}, due to clock errors, long-term changes in the instrument, and so on, as well as a statistical contribution τ_{st} which is roughly proportional to $n^{-1/2}$, where n is the number of pulses observed. The relative accuracy for the period determination is therefore

$$A = \delta P/P = 2\tau/T \qquad (1)$$

In order to find a period change, one has to subdivide the sample into at least two groups. A period change within the time $\sim T/2$ can be determined with roughly the accuracy (relative to the period)

$$B = \delta(\Delta P)_{T/2}/P = 2 \times 2\tau/(T/2) \qquad (2)$$

as long as the observations cover about uniformly the whole interval T. The period change per period is related to the period change in the time T by $(\Delta P)_P = (\Delta P)_T P/T$.

The rate of period change is therefore given with an absolute accuracy of

$$C = \delta\dot{P} = \delta(\Delta P)_P/P = (\delta(\Delta P)_{T/2}/P) \times P/(T/2) \qquad (3)$$

We apply these formulae to the example given in ref. 1. They assume daily observing periods of $T = 10^4$ s $= 2{\cdot}8$ h each, with $P = 0{\cdot}1$ s, $\tau = 10^{-4}$ s. For the sake of simplicity, let us assume that τ is independent of n, the total number of pulses observed. For one day's observations, we find that A (2·8 h) $= 2 \times 10^{-8}$, B ($2 \times 1{\cdot}4$ h) $= 8 \times 10^{-8}$ and C ($2 \times 1{\cdot}4$ h) $= 1{\cdot}6 \times 10^{-12}$. For two days' observations, separated by one month, we find that A (30 days) $=$ 8×10^{-11}, B ($2 \times 2{\cdot}8$ h; 30 days) $= 2$ A (2·8 h) $= 4 \times 10^{-8}$ and C ($2 \times 2{\cdot}8$ h; 30 days) $= 1{\cdot}6 \times 10^{-15}$. For thirty consecutive days' observations, we find that A (30 days) $=$ 8×10^{-11} as in the previous case, while B (2×15 days) $=$ 3×10^{-10} and C (2×15 days) $= 2{\cdot}5 \times 10^{-17}$.

In order to compare our estimates with actual measurements, we mention the Crab pulsar[4] and the Vela pulsar[2]. Within several weeks, their periods P were determined with a relative accuracy of 10^{-10} and 10^{-11} while their rates of period change $\dot{P}$ were determined with an absolute accuracy of 8×10^{-18} and 2×10^{-19}.

In ref. 1, the numbers A (2·8 h) and C ($2 \times 2{\cdot}8$ h; 30 days) were given. The latter number was compared with the apparent pulsar–period change of about 8×10^{-15} P due to a change in Doppler effect from a change of $\sim 0{\cdot}5$ ms in the length of a day. One should rather use B (2×15 days) for the comparison. On the other hand, if this change of period occurs within 15 days, the mean rate of period change $\dot{P}$ is about 6×10^{-22}. This number should be compared with C (2×15 days).

The easiest way to see that the effect simply cannot be detected is the following: when the day has been longer by 0·5 ms for 15 days, then the accumulated effect on the pulse arrival time at the rising time of the pulsar is only about 10 ns while the assumed timing precision for a combination of ~ 4 pulses is about 400 μs. The three methods of analysing the problem in terms of either arrival times, or periods, or rates of period change are equivalent, however. The ratios of accuracy to expected effect are the same in each case, that is

$$\frac{400\ \mu\text{s}}{10\ \text{ns}} = \frac{B\,(2 \times 15\ \text{days})}{8 \times 10^{-15}} = \frac{C\,(2 \times 15\ \text{days})}{6 \times 10^{-22}}$$

We conclude that even with better timed and more extended pulsar measurements, there is little hope to detect changes in the length of a day smaller than about 100 ms.

On the Connexion between Pulsars and Supernovae

I REPORT here some preliminary results of a statistical study of the spatial distribution of pulsars in the galaxy which have direct relevance to the pulsar–supernova hypothesis and to certain features in the observed distribution of pulsar galactic latitudes. I present evidence that most pulsars may have been formed in Type II supernova explosions and initially possessed extremely high velocities, of order 1,000 km s^{-1}. On this basis, four new pulsar–supernova identifications are suggested.

Some time ago Large *et al.*[1,2] reported that the pulsars tended to cluster a few degrees south of the galactic plane, while Davidson and Terzian[3] noted a complete absence of pulsars between $b^{\rm II} = +6°$ and $+25°$. Since that time, the former effect has persisted, suggesting that it is real, but a couple of new pulsars (MP 1706, JP 2021) have been found in the underpopulated band, suggesting that the latter effect was due to observational selection.

A natural explanation of the apparent clustering of pulsars south of the galactic plane arises if we are willing to assume that most pulsars found to date are nearby (within 1 kpc) and possess a plane of maximum density that is coincident with the plane of maximum density of local young optical Population I objects. The pulsar distance estimates of Prentice and ter Haar[4,5] and others certainly support the assumption of nearness, while $\dot{P}/P$ measurements[6–8] yield typical pulsar lifetimes of 10^7 yr, which is young. Now Blaauw *et al.*[9] conclude that the Sun lies at a height $z_0 = 22 \pm 2$ pc above the mean plane defined by the local distribution of OB stars and cepheids. Letting z' be the height in pc above this plane our assumption is that the pulsar density $\rho(z')$ is maximum at $z' = 0$. A reasonable fit to the data is then

$$\rho(z') = \rho_0 \exp(-|z'|/110) \qquad (1)$$

We found for the mean height 110 ± 20 pc, which agrees with Mills's[10] figure of 110 pc. A simple calculation now yields that $\rho(b^{\rm II})$, the distribution with galactic latitude, $b^{\rm II}$, of all pulsars counted within a sphere of radius R centred on the Sun, has a sharp maximum at $b^{\rm II}_{\rm max}$ given by

$$\sin(b^{\rm II}_{\rm max}) = -2z_0/R$$

Substituting $z_0 = 22$ pc and $R = 1{,}000$ pc we find $b^{\rm II}_{\rm max} = -2{\cdot}5°$ which is in good agreement with the value $-2{\cdot}5 \pm 1°$ deduced from the observational data.

We now turn to the more important question regarding the pulsar–supernova hypothesis, that is that pulsars are created in supernova explosions. The reason why it is important to investigate this hypothesis is that Gold[11] suggested that pulsars would be rotating neutron stars, for which there are also strong indications based on the magnitude of the pulsar period. On the other hand, Cameron's recent considerations[12] have shown that the previously generally accepted connexion between neutron stars and supernovae explosions[13] meets with grave theoretical difficulties[14,15]. It should be mentioned that so far two, but no more, pulsars have been successfully associated with supernovae.

Using the pulsar distances of Prentice and ter Haar[5], the galactic spatial distribution of forty-two pulsars has been compared with observational data on local distributions of hot OB stars, O to B5 open galactic clusters and associations, O to B5 supergiants and "runaway" stars, and supernova remnants. The following facts emerge.

(i) Setting aside known selection effects due to instrumental limitation (for example, field-of-view and dispersion measure restriction), the distribution in galactic longitude and distance in the plane is essentially random and isotropic. In particular, there is no suggestion of aggregation along the "optical" spiral arms of the galaxy[16–18]; this differs from the conclusions reached by Davidson and Terzian[3] and by Mills[10].

(ii) Within 1 kpc of the Sun there is no significant correlation between the positions of pulsars and those of the hot O stars, O to B5 supergiants and O to B5 "runaway" stars.

(iii) Of the sixteen known supernova remnants within about 2 kpc that are catalogued by Poveda and Woltjer[19], and forty-two pulsars under investigation, there were nine instances (see Table 1) where a pulsar lay within 6° of a remnant site, while the distance estimates for pulsars and supernova remnants were compatible. The chance that this event should arise on a null pulsar–supernova association hypothesis was estimated to be less than 0·005. For the remaining supernova remnants and pulsars there was very little positional coincidence.

Table 1. PULSAR–SUPERNOVA ASSOCIATIONS

Supernova remnant	Pulsar	θ/d	r	t_p (10^4 yr)	t_s (10^4 yr)	Association indicated
Crab Nebula	NP 0532	0 ?	1·3	0 ?	(0·1)	Yes
Crab Nebula	NP 0527	16	1·2	6	(0·1)	No
Sh 147	NP 0527	1·7	1·3	24	25	Yes
Vela X	PSR 0833–45	0·26	0·8	1	1	Yes
Vela X	MP 0835	2·4	0·8	10	1	No ?
Vela Y	MP 0835	2·0	0·3 ?	18	7	Yes ? ?
P 1439–62	MP 1449	3·5	> 0·4	25	4	Yes ?
W 28	PSR 1749	11	0·8	25	0·3	No
HB 21	JP 2111	2·8	1·3	23	6	Yes ?

What conclusions can be drawn from this ? We note first that the mean pulsar height $<|z|> = 110$ pc (see equation (1)) is significantly higher than the value 57 pc appropriate to galactic clusters[17], the value 76 pc to all local O to B5 stars[20], and the value 64 pc found for supernova remnants, thought to be mostly Type II, having $|z| < 300$ pc (ref. 19). It is, however, comparable with that of the O to B5 "runaway" stars ($<|z|> \sim 100$ pc, ref. 22), which have been studied in great detail by Blaauw[21]. Because the mean height of pulsars with $|z| < 300$ pc is still greater than 100 pc, we cannot attribute the high $<|z|>$ to the Type I supernovae which Poveda and Woltjer found deficient in our galaxy. The OB "runaway" stars are known to have acquired a high z in their short lifetime ($\sim 10^7$ yr) by virtue of their very high velocities, typically 100 km s^{-1}. Thus because the pulsars are probably also young, we may infer that they too, perhaps, possess very high velocities. In view of Blaauw's suggestion that runaway stars originate in the supernova explosion of a binary companion, we consider it not unreasonable to assume that the kinematic properties of pulsars and "runaway" OB stars bear a resemblance, and we shall assume that the pulsars move with these high velocities unimpeded by the deceleration processes in the interstellar medium which slow down the supernova remnants. A suggestion which seems attractive is that the pulsar leaves an asymmetric Type II supernova explosion with a velocity of the order of 1,000 km s^{-1}.

As Poveda and Woltjer have shown that the supernova remnants clearly delineate the local "optical" spiral arms, (i) also implies that, if the pulsar–supernova hypothesis is correct, the pulsars possess high speeds. As the distance between arms is approximately 2 kpc, the pulsars need a minimum average speed of 100 km s^{-1} in order to lose all identity of origin within a lifetime of 10^7 yr.

The final piece of evidence (iii) allows us to accept the hypothesis of the pulsar–supernova association at a very high level of significance. It is, at the same time, consistent with the hypothesis of intrinsically high pulsar velocities. These two hypotheses, in fact, go hand in hand, because a minimum speed of 200 km s^{-1} is necessary to explain the complete absence of pulsars inside the older supernova remnant shells—the oldest known remnants have ages of about 2×10^5 yr and radii of about 40 pc (ref. 19).

The test case of our arguments is the young pulsar PSR 0833–45 discovered by Large *et al.*[23] inside the Type II supernova remnant Vela X. Taking the distance estimate[24] of 500 pc, and age estimate[25] 1×10^4 yr, the observed angular separation between PSR 0833–45 and the centre of Vela X implies a minimum velocity of separation of 500 km s^{-1}. This means that the pulsar should leave Vela X after not greater a period than 3×10^4 yr, which is a time well inside the observational lifetime of the remnant.

Accordingly, there is very good reason to hope that some of the nine instances mentioned under (iii) are real pulsar–supernova associations. To proceed a little further the ages of the remnants and independently those of the suspected pulsars were computed using the PSR 0833–45—Vela X identification as a yardstick. The results are shown in Table 1. In the table, θ/d is the ratio of pulsar–supernova angular separation to supernova angular diameter and r the ratio of the estimated[5] pulsar to catalogued[19] supernova distance. The pulsar age t_p was computed by extrapolating θ back to 0 with a transverse pulsar velocity of 500 km s^{-1} and is subject to a large uncertainty, principally because we have no knowledge of the velocity along the line of sight. The supernova age was computed from the formula $t_s \propto R_s^{5/2}$ (ref. 22, p. 170) normalized against Vela X, R_s being the remnant radius. The only physical justification we have for making a uniform calibration is that, excepting the Crab Nebula, all of the supernova remnants listed are probably of the same type, that is, Type II (ref. 22, pp. 141, 160).

I want to make a few comments on the results of Table 1.

(i) The Crab supernova, apart from being Type I, is too young for a time t_s to be defined. Also, it is so young that if NP 0532 had been lying outside the remnant, we would have had difficulty in associating it with the Crab supernova.

(ii) It seems to us that NP 0527 should not be associated with the Crab supernova, but rather with Sh 147. It is interesting that the pulsar with the longest period would then be associated with the oldest supernova remnant, although the age of Sh 147 is probably only about 250,000 yr, which is much shorter than the suggested lifetimes of about 10^7 yr for old pulsars.

(iii) If one accepts Milne's[24] suggestion that Vela Y and Vela X are both parts of the same supernova remnant at a distance of about 500 pc, the value of r for MP 0835 becomes 0·8 and t_p to Vela Y, 7×10^4 yr.

(iv) The distance of MP 1449 is only a lower limit. It is interesting to note that MP 1449 is the pulsar with the third shortest known period. From Goldreich's theory[26] one obtains a lifetime of about 40,000 yr which agrees well with $t_s \sim 4 \times 10^4$ yr.

I thank Dr D. ter Haar for reading the manuscript and for helpful suggestions, and other members of the Department of Theoretical Physics for discussions. I also thank both the Royal Commission for the Exhibition of 1851 and Wolfson College, Oxford, for generous support.

Variations of Linear Polarization in Extragalactic Radio Sources

SINCE mid-1965 the linear polarizations of the stronger extragalactic variable radio sources have been monitored at 8 GHz using the University of Michigan 85-foot paraboloid equipped with a rotating, linearly polarized feed horn. Strong thermal and non-thermal sources were measured each observing day to determine the stability of the instrumental polarization. Five sources, 3C 120, 3C 273, 3C 279, 3C 345 and 3C 454·3, have exhibited significant changes in polarization, and three sources, 3C 84, NRAO 150 and 3C 446, are suspected of having variable polarizations. Preliminary observational results for several of these sources have been reported previously[1,2].

The general characteristics of the observed variations in polarization are as follows: (1) They do not mimic the variations in the total flux densities; (2) they occasionally have time scales as short as one week, which are much less than the time scales of the variations in the total flux densities of these sources; (3) their amplitudes are as large as 5–10 per cent of the amplitudes of the variations in total flux density; (4) large, rapid changes in polarization have been observed only when the total flux density was increasing or had reached a maximum; (5) variations in both the position angle of the plane of polarization and in the degree of polarization have been observed.

I wish to point out that these characteristics of the observed variations in polarization are consistent with expanding source type models (for example, ref. 3) and do not require any special source geometry except that the magnetic fields in these sources be relatively well ordered. In these models the low frequency cut-off in flux is produced by synchrotron self-absorption. As the source expands, the total absorption depth through the source decreases and the flux reaches a maximum at any frequency ν shortly after τ_ν (the absorption depth averaged over all polarizations) reaches unity in the source. Two processes which cause variations in polarization and which apparently have not been reported before occur as a result of this decrease of τ_ν with time.

Process I is the change with τ_ν of the intrinsic polarization of a synchrotron source. From the expressions for the emission and absorption coefficients of the synchrotron mechanism[4], it may be shown that when $\tau_\nu \gg 1$ the intrinsic degree of linear polarization is $3/(6\gamma+13)$ (ref. 5) with the plane of polarization parallel to the magnetic field. γ is the negative exponent in the electron energy-density power-law relation. This state of polarization is different from the case which is usually discussed of $\tau_\nu \ll 1$ when the intrinsic plane of polarization is perpendicular to the field, and the intrinsic degree of polarization is $(3\gamma+3)/(3\gamma+7)$. Studies of the variable sources 3C 120 (ref. 6) and 3C 273 (ref. 7) indicate that $\gamma \sim 1{\cdot}5$ for these sources. For this value of γ the intrinsic degree of polarization changes rapidly with τ_ν over the range $0{\cdot}5 \lesssim \tau_\nu \lesssim 10$ and equals zero (where the plane of polarization changes by 90 degrees) at $\tau_\nu \sim 5$. Thus even in the unrealistic case that the magnetic field was oriented in the same direction throughout the emitting region, an expanding source would exhibit variations in polarization as the source passes through the phase where $10 \gtrsim \tau_\nu \gtrsim 0{\cdot}5$. This phase occurs immediately before the expanding source reaches maximum flux output at the frequency ν.

Process II arises when the orientation of the magnetic field is not constant throughout the emitting region of the source. The observed polarization of a source is the average of the contributions of all polarized emitting regions within the source and thus depends upon the absorption depth of each region. As τ_ν decreases with time the contribution to the observed polarized radiation of emitting regions situated deep within the source increases. The observed polarization will then change because the states of polarization of different regions within the source are not the same. The rate of change of the observed polarization depends on the amplitude of $d\tau_\nu/dt$ and would generally be largest when $\tau_\nu \gtrsim 1$. Relatively rapid changes in polarization produced by this process do not require the magnetic field in the source to have small scale structure.

Both processes I and II are only important for $\tau_\nu \gtrsim 1$ and do not produce appreciable variations when $\tau_\nu \gg 1$ or $\tau_\nu \ll 1$. Thus the fact that large, rapid changes in polarization have been observed only during periods when $\tau_\nu \gtrsim 1$ (according to the expanding source model) strongly suggests that one or both of these processes are the chief cause of the observed variations in linear polarization. Neither process depends on changes in the structure of the radiating region (aside from overall expansion) or on any particular source configuration in order to produce polarization variations. Also the relatively well ordered structure of the magnetic field required to account for the large amplitudes of the polarization variations is not inconsistent with the rapid variations being produced by these processes. A detailed description of the observational results and the interpretation of the observed polarization variations is in preparation.

I thank W. A. Dent for pointing out that the plane of polarization of an opaque synchrotron source is parallel to the magnetic field, and F. T. Haddock for many discussions. This work was supported in part by the US Office of Naval Research and by the US National Science Foundation.

Primordial Synthesis of Superheavy Nuclei in the Galaxy

ASTROPHYSICAL evidence in favour of the thesis that an appreciable amount of the heavy elements was produced in a giant explosion in the nucleus of the galaxy about 7×10^9 yr ago has been given by Unsöld[1]. Cosmochemical arguments could support Ambartsumyan's concept[2] of the presence of massive bulks of prestellar matter in the nuclei of the galaxies. The latter concept has now received further support from the calculations of Saakyan and Mnatsakanyan[3], who have reported on the possibility of hydrostatic equilibrium of superdense matter bulks of arbitrary mass in the framework of a slightly modified general relativity theory with variable gravitational constant G.

Synthesis of heavy elements in exploding massive bulks of prestellar matter may go preferentially through some kind of neutron capture process, similar in principle to those going on in stars. This synthesis occurs predominantly in the external layers of the body, where the density of matter drops below a subnuclear value of 10^{13} g cm^{-3} and the matter exists in the so-called "neA" phase (neutrons, electrons, nuclei). Synthesis of nuclei up to uranium in such high density conditions (without specifying whether this occurs in stars or in other objects) has been considered by Amiet and Zeh[4]. The shift of the valley of beta-stability of nuclei in the (Z,N) plane towards the N-axis at higher densities made it possible to bypass the α-instability region. At the time when these results were reported there were still no explicit results on the possible island of stability near $Z = 114$, and it was not necessary to extend the neutron capture tracks up to that region.

There has been much theoretical work on the region near the doubly closed shell nucleus $^{298}114$, and it was found that the nuclide $^{294}110$ might be the best-fitted candidate for survival (see ref. 5, which contains a list of references on the properties of superheavy nuclei). A half-life exceeding 2×10^8 yr cannot be excluded *a priori*. Experimental searches for this and closely related elements are in progress; there are certain indications in favour of extinct superheavy elements in meteorites. The evidence comes from isotopic anomalies in the Xe and Kr composition[6]. We have to deal here with the effect of symmetric fission. It may be added that in the region from tellurium to rare earths we find some characteristic abundance irregularities: several odd isotopes of even elements (such as Xe, Sm, Gd, Dy) are more abundant than their even neighbours. These more abundant isotopes are unshielded from the side of proton-deficient nuclides, and thus their relative overabundance may be regarded as a mere consequence of fission product β⁻-decay chains from the fission of superheavy elements. This indirect evidence for extinct superheavy elements makes the search for the last relics from an island of quasi-stability more promising.

In such a search we must be guided by some ideas resulting from the way in which we understand the mechanism of synthesis. In addition to the probably single event of synthesis in the explosion in the galactic core, the continuous mechanism of production in supernova explosions should be taken into account. A lower estimate of the production of about 10^{32} nuclei of the element 110 per second in the galaxy by the mechanism of supernovae explosions was obtained[7]. It would be interesting to estimate the production in the explosion of the galactic core; it is possible, in principle, to have here a larger time scale and a much higher neutron flux. Because the prestellar matter bulks are relativistic objects, detailed results should be obtained within the theory of relativity which will determine the time scale of the process. Such calculations will be made in the future, and it is possible now to remark only that their results should be compared with observational abundances of the superheavy elements and with such abundance peculiarities as those discussed. It is possible that observational results on the abundance of the element 110 would help to decide whether Unsöld[1] was right in accentuating the role of explosions in galactic nuclei for the synthesis of heavy elements.

Two New Plasma Instabilities in the Solar Wind

IN this communication we consider the left-hand mode in a hot plasma, propagating in the direction of the average magnetic field, and for frequencies near the proton gyrofrequency we find two new instabilities. The first is driven by strong electron thermal anisotropy and the second by strong proton thermal anisotropy in the presence of electron anisotropy. We believe that the first of these new instabilities may have important consequences for the development of the solar wind. This mode is similar to the low-frequency firehose instability but it involves only the electron anisotropy. The wavelength is short, and the destabilizing centrifugal force on the electrons is able to overwhelm the cyclotron damping due to the resonant protons. If this instability occurs in the solar wind, it results in an additional coupling between the electrons and protons, with the result that it can contribute to the proton heating.

Considering a hydrogen plasma, Stix's dispersion relation[1] for circularly polarized electromagnetic waves propagating in the direction of the average magnetic field, B_0, may be written in the form

$$k^2 v_A^2 + \Omega_e \Omega_p A_e + \Omega_p^2 A_p = i(\Omega_e \Omega_p / v_e) F_0(\alpha_{\mp e}) \times$$

$$\left[\frac{\omega}{k} - v_e A_e \alpha_{\mp e}\right] + i(\Omega_p^2 / v_p) F_0(\alpha_{\pm p}) \left[\frac{\omega}{k} - v_p A_p \alpha_{\pm p}\right] \qquad (1)$$

Our calculations are in the rest system of the plasma; the results in other systems are simply Doppler shifted in the usual way. The subscripts p and e refer to the protons and electrons respectively. v_p is the thermal velocity of the protons, based on their temperature parallel to the magnetic field: $v_p = (2KT_{\parallel}^{(p)}/m_p)^{1/2}$. Their thermal anisotropy is given by $A_p = 1 - T_{\perp}^{(p)}/T_{\parallel}^{(p)}$. The proton gyrofrequency is $\Omega_p = qB_0/m_p c$ where q is the proton charge. $\alpha_{\pm p}$ is defined by

$$\alpha_{\pm p} = \frac{\omega \pm \Omega_p}{k v_p} \qquad (2)$$

The quantity $v_A = (B_0^2/4\pi n m_p)^{1/2}$ is the Alfvén speed, where n is the proton concentration. Analogous definitions hold for the electrons, and we define $\Omega_e = (m_p/m_e)\Omega_p > 0$. As usual, ω, k and c are the angular frequency (assumed complex), the wave number (assumed real), and the speed of light, respectively; all wave quantities are assumed to vary as $\exp(ikx - i\omega t)$. F_0 is the plasma dispersion function

$$F_0(s) = -(i/\pi^{1/2}) P \int_{-\infty}^{+\infty} \frac{e^{-z^2}\,dz}{z - s} + \pi^{1/2}\,\mathrm{sgn}\,(k) e^{-s^2} \qquad (3)$$

We consider the left-hand mode, taking the lower sign in equation (1). For frequencies near the proton gyrofrequency, equation (2) suggests that we should seek solutions for which the approximations

$$\alpha_{-p} \ll 1; \;\; \alpha_{+e}^2 \approx \left(\frac{\Omega_e}{k v_e}\right)^2 \gg 1 \qquad (4)$$

are valid. Expanding F_0 accordingly[1] yields for the protons

$$F_0(\alpha_{-p}) \cong \pi^{1/2}\,\mathrm{sgn}\,(k) \exp(-\alpha_{-p}^2) + 2i\alpha_{-p}(1 - 2\alpha_{-p}^2/3 + \ldots) \qquad (5)$$

and for the electrons

$$F_0(\alpha_{+e}) \simeq i\alpha_{+e}^{-1}(1 + 1/2\alpha_{+e}^2 + \ldots) \qquad (6)$$

From equations (1), (5) and (6) we then obtain

$$k^2(1 + \xi_e) = \frac{\Omega_p^2}{v_A^2} \left\{ -(1 + A_p) + \frac{i\pi^{1/2}}{kR_p} - \alpha_{-p}\left[\left(kR_p + \frac{2}{kR_p}\right) - i\pi^{1/2}\,\mathrm{sgn}\,(k)(1 - A_p)\right]\right\} \qquad (7)$$

where $R_p = v_p/\Omega_p$ is the proton gyroradius, and ξ_e represents the electron anisotropy

$$\xi_e = 4\pi nK(T_\perp^{(e)} - T_\parallel^{(e)})/B_0^2 \tag{8}$$

We note that $|\xi_e|$ can differ significantly from zero even for small temperature anisotropies, if $4\pi nKT_\parallel^{(e)} \gg B_0^2$; such a situation prevails in the solar wind. In deriving equation (7) we have consistently kept terms only to the first order in α_{-p}.

Equation (7) may be solved for $R_e(\alpha_{-p})$ and $\mathrm{Im}(\alpha_{-p})$. The results are complicated, however, and we confine our attention to cases where

$$k^2R_p^2 \gg 1 \tag{9}$$

We find that consistent solutions are obtained for this case. Inequality (9) must, however, be considered in the context of inequality (4*b*). Taken together, they require

$$\frac{m_p}{m_e} \; \frac{T_p}{T_e} \gg k^2R_p^2 \gg 1 \tag{10}$$

If T_e/T_p is less than about 10 (as is the case in the solar wind, for example), we expect that $k^2R_p^2$ will be able to satisfy both requirements in (10) simultaneously.

From equation (7) one obtains for the real part ω_r (assumed positive) and the imaginary part ω_i of the frequency

$$\frac{\omega_r}{\Omega_p} + A_p \cong -k^2R_p^2(v_A^2/v_p^2)(1+\xi_e) \tag{11}$$

$$\frac{\omega_i}{\Omega_p} \cong (\pi^{1/2}/k|R_p)\left[A_p + \frac{\omega_r}{\Omega_p}(1-A_p)\right] \tag{12}$$

Equations (11) and (12) are the desired solutions of the dispersion relation, and we distinguish two cases.

First (case I) let us suppose that $T_\perp^{(p)}/T_\parallel^{(p)}$ is small enough for

$$\frac{\omega_r}{\Omega_p} + A_p > 0 \tag{13}$$

This will be the usual case in the solar wind. Then equation (11) tells us that we must require

$$1+\xi_e < 0 \tag{14}$$

for a solution, because k is real. But we have assumed $k^2R_p^2$ to be large, and from equation (11) this usually further requires

$$|1+\xi_e| \ll 1 \tag{15}$$

We thus find that the existence of this wave depends critically on the perpendicular electron temperature being sufficiently smaller than the parallel temperature so that (14) holds, but that there is a limit to how much smaller it can be if one of our assumptions is not to break down.

The wave propagates much more slowly than the Alfvén velocity, in virtue of the largeness of k.

ω_i can be written in terms of ω_r as follows

$$\frac{\omega_i}{\Omega_p} \cong \pi^{1/2}(v_A/v_p)\left[A_p + \frac{\omega_r}{\Omega_p}(1-A_p)\right] \left(A_p + \frac{\omega_r}{\Omega_p}\right)^{-1/2}|1+\xi_e|^{1/2} \tag{16}$$

The waves always grow (that is, ω_i is always positive) if the basic condition (13) is fulfilled. We thus suggest that (14), that is, the condition for the existence of the waves, represents the real instability criterion, and that the waves are therefore driven by the electron anisotropy.

This instability is thus similar to the low frequency firehose instability[2,3] but, in contrast, the proton anisotropy does not appear in the present instability criterion because we have assumed frequencies in the vicinity of the proton gyrofrequency. The wave is destabilized by the centrifugal force felt by the electrons as they move along the perturbed magnetic field. The centrifugal force increases with increasing k, and, for the large k values assumed here, overwhelms the damping effect due to the resonant ions, which decreases like k^{-1}. We expect, in fact, that the growth rate of the instability can be larger than that of the low frequency firehose, and this instability may therefore be of greater significance.

Do these waves exist in the solar plasma? Direct measurements of the electron thermal anisotropy are unreliable. Parker[4] has pointed out in a recent review, however, that direct measurements of high frequency ($>10^{-2}$ Hz) fluctuations in the solar wind suggest the existence of an internal instability. The firehose is favoured, but Parker argues that the electrons must contribute substantially to its excitation, because the protons cannot drive the firehose alone. This implies that ξ_e must be close to -1. Whether ξ_e is in fact less than -1 cannot at present be decided, but this is a viable possibility.

The presence of the unstable left-hand mode in the interplanetary plasma may have important consequences. Because the instability is driven by the electron anisotropy, energy will go from the electrons into the wave. But the wave is resonant with the protons, and we expect the wave to give up some energy to the perpendicular motion of the protons. The result will be a (partial) transfer of thermal energy from the electrons to the protons. Now, recent work by Burlaga and Ogilvie[5] indicates that the two-fluid solar wind model of Hartle and Sturrock[6] represents an extremely quiet situation, and that the solar wind typically exhibits proton temperatures and bulk velocities which are higher than those calculated by Hartle and Sturrock. This implies that some heating of the protons usually occurs. There is also an indication that the electron temperatures calculated by Sturrock and Hartle are somewhat higher than those observed, although it is not clear whether the difference is significant. We believe that the transfer of energy from electrons to protons may provide a suitable heating mechanism for the solar wind protons. Furthermore, the energy goes into the motion of the protons perpendicular to the magnetic field, which may help to explain why, in the solar wind, $T_\perp$ is not as small as might be expected on theoretical grounds[7]. We plan to discuss these points in detail in future publications.

Referring once again to equation (11), consider the situation where $T_\perp^{(p)}/T_\parallel^{(p)}$ is sufficiently large (case II) that

$$\frac{\omega_r}{\Omega_p} + A_p < 0 \tag{17}$$

Then an allowed solution for (11) exists only if

$$1+\xi_e > 0 \tag{18}$$

The wave number k can then be found from equation (11); we see that if $k^2R_p^2$ is to be large, according to the assumption, we will usually require

$$0 < 1+\xi_e \ll 1 \tag{19}$$

This wave exists in the absence of electron anisotropy, but some anisotropy is usually necessary to satisfy the assumption of large k. This situation contrasts with the previous case where electron anisotropy was necessary for the existence of the wave.

The propagation speed is again much less than the Alfvén speed.

The growth rate is the same as in case I, equation (16), with the exception that $(A_p+\omega_r/\Omega_p)$ must be replaced by its modulus. The instability criterion is

$$A_p + \frac{\omega_r}{\Omega_p}(1-A_p) > 0 \qquad (20)$$

subject to inequality (17). These requirements are plotted simultaneously in Fig. 1.

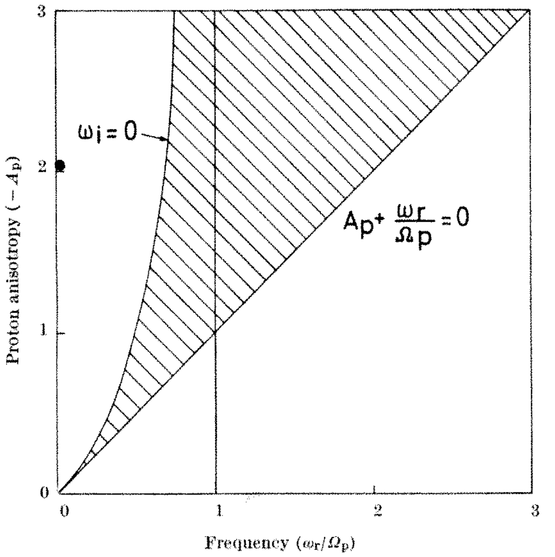

Fig. 1. Plot of the proton temperature anisotropy, $-A_p$, against frequency, for case II. The hatched area represents the region for wave growth (upper curve) subject to the requirement defining case II, $A_p+\omega_r/\Omega_p<0$.

This instability is driven by perpendicular proton temperatures sufficiently in excess of the parallel temperatures. We expect that it will be important primarily for laboratory plasmas, although it may occur in the solar wind in local regions where $T_\perp^{(p)} > T_\parallel^{(p)}$.

Identification of the ν_3 NO_2 Band in the Solar Spectrum observed from a Balloon Borne Spectrometer

SINCE the detection of HNO_3 in the atmosphere[1], it has been expected that oxides of nitrogen, such as NO_2, should also be present. In fact, in a previous paper by some of us[1] a tentative identification of NO_2 absorption was made. The most intense vibration–rotation band of NO_2 is the ν_3 fundamental, centred at 1,618 cm^{-1}, near the centre of the ν_2 H_2O band.

In this region, the solar spectrum[2] as observed from a balloon borne spectrometer at float altitude (30 km), while the Sun was setting, reveals a series of weak lines which occur among the well known H_2O lines. For example, a number of weak lines are observed on both sides of the normally isolated $1_{-1}-1_1$ H_2O line at 1616·8 cm^{-1}. Many more lines can be seen in this region, and on closer examination a faint band envelope can be observed centred near 1,618 cm^{-1}. These additional lines also show some absorption in high altitude spectra measured at zenith angles smaller than those obtained during the sunset.

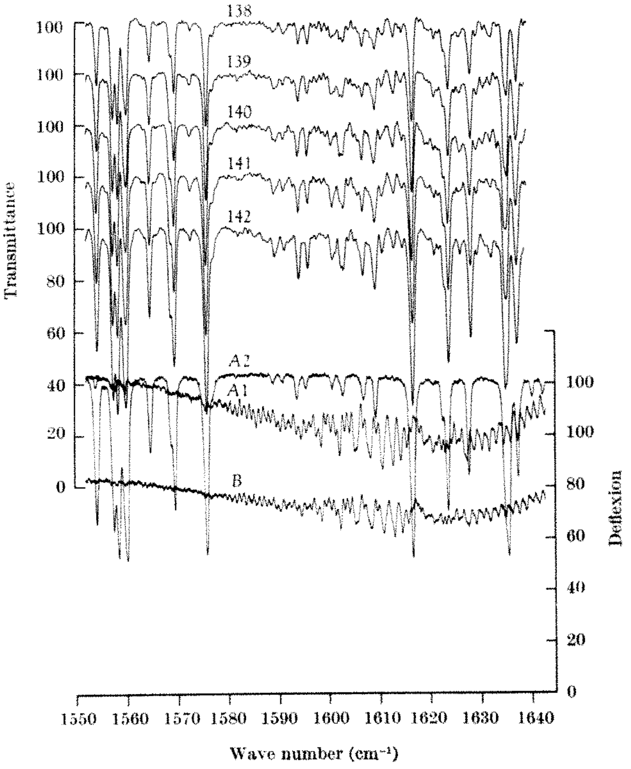

Fig. 1. Identification of the ν_3 NO_2 band. Records 138–142: sunset balloon spectra (reproduced from ref. 2). *A*, Spectrum of NO_2 obtained from reagent grade red fuming nitric acid supplied by Baker Co. (curve 1) and the corresponding portion of the ν_2 H_2O spectrum (curve 2). *B*, Spectrum of CP grade NO_2 from Matheson Co., at a pressure of 2·5 mm Hg.

Laboratory spectra of the ν_3 region of NO_2 have been taken under a resolution of ~0·5 cm^{-1}, which is similar to the resolution obtained during the balloon flight. The corresponding portion of the ν_2 H_2O spectrum was recorded for comparison.

The laboratory spectra were obtained on a double-beam Beckman infrared spectrophotometer, model IR7, using a 10 cm glass absorption cell with AgCl windows, at 40° C. A Kel-F halocarbon oil manometer was used for pressure measurements.

The results are shown in Fig. 1, in which the relevant portion of the sunset solar spectrum is reproduced from ref. 2, along with two laboratory spectra of the ν_3 NO_2 band. In sample *A*, curve 1 represents absorption by NO_2 vapour generated from reagent-grade red fuming nitric acid, supplied by J. T. Baker Chemical Co. This sample shows traces of H_2O lines probably due to residual H_2O vapour used to record the ν_2 H_2O lines (curve 2). Sample *B* is CP grade NO_2 from the Matheson Co. The two spectra agree qualitatively with that of Arakawa and Nielsen[3].

The NO_2 and H_2O line complexes were checked against the solar spectrum, and the NO_2 lines were found to match, both in position and intensity, the line structure which is additional to the H_2O lines. The centre of the NO_2 band envelope is masked by the $1_{-1}-1_1$ H_2O line, but the NO_2 line structure is clearly identified. The weak line at 1,574 cm^{-1} is probably due to ν_2 HDO.

This research was supported by the Advanced Research Projects Agency and was monitored by the Air Force Cambridge Research Laboratories.

Crystal Chemistry of the Plagionite Group

LEAD forms a large number of complex sulphosalts. At least twelve Pb–As and nineteen Pb–Sb sulphosalt minerals are known[1] and, although the Pb–As minerals have received considerable study, no structure for a Pb–Sb sulphosalt has been completely determined. Curiously, minerals in the two systems exhibit little similarity in either composition or lattice constants in spite of the fact that isomorphism and even complete solid solubility are found for a number of arseno- and antimonian sulphosalts. This is undoubtedly due to the rather different sizes of As and Sb coordination groups relative to the dimensions of a Pb–S polyhedron.

Table 1. THE PLAGIONITE GROUP

		a (Å)	*b* (Å)	*c* (Å)	*β*	Ref.
Fülöppite	$Pb_3Sb_8S_{15}$	13·39	11·69	16·91	94° 41′	2
Plagionite	$Pb_5Sb_8S_{17}$	13·4857	11·8656	19·9834	107° 10′	Present work
Heteromorphite	$Pb_7Sb_8S_{19}$	—	—	—	—	*
Semseyite	$Pb_9Sb_8S_{21}$	13·64	12·01	24·57	105° 49′	4

* Crystals of heteromorphite are extremely rare and are invariably distorted. No accurate X-ray or morphological data exist. The mineral was placed in the plagionite group by Spencer[3] on the basis of its composition and approximate goniometric measurements.

Minerals of the plagionite group (Table 1) form a particularly interesting series. No As analogues occur and the known members of this group form an apparent homologous series, $Pb_{3+2n}Sb_8S_{15+2n}$ with $n=0$ to 3. Two lattice constants remain invariant throughout the group, while c increases uniformly with n. The probable space group for all of the phases is $C\ 2/c$ and $Z=4$. We are investigating the crystal structures of these minerals and we have completed a study of plagionite. An analysis of semseyite is in progress. We wish to present a preliminary description of the plagionite structure; its features suggest the probable relation between the structures of the other members of this family.

A plagionite crystal from Wolfsberg, Harz, Germany (Harvard Museum Catalogue No. 11391), was ground into a sphere of 0·054 mm radius ($\mu r=6{\cdot}51$ for Cu$K\alpha$ radiation). Precession photographs identified the diffraction symbol as $2/m\ C\ -/c$, which permits Cc and $C\ 2/c$ as space groups. The morphology of the mineral suggested the centric option and this was subsequently confirmed by statistical tests. Least-squares analysis of measurements obtained from back-reflexion Weissenberg films provided the lattice constants presented in Table 1. A complete three-dimensional set of diffracted intensities was obtained with the aid of an equi-inclination Weissenberg diffractometer equipped with a proportional counter; 2,953 of the 3,579 independent reflexions available in the Cu$K\alpha$ sphere were accessible with the instrument used. The intensities were very weak, the maximum peak height of any reflexion recorded being less than 500 counts/s, and as a result 651 of the accessible reflexions were undetectable.

The structure of plagionite was solved by the symbolic addition procedure. A total of 633 signs were determined at probability levels greater than 0·989 from among the 950 largest ($E\geq 0{\cdot}83$) normalized structure factors. An E-map revealed locations for all metal atoms. Positions for sulphur atoms were suggested by this map, but their location was deferred to subsequent electron density maps based on signs computed from the metal atom positions. We have refined the structure by least-squares techniques to a disagreement index of 18 per cent.

Table 2. ATOMIC POSITIONS AND TEMPERATURE FACTORS IN PLAGIONITE (STANDARD DEVIATIONS IN PARENTHESES)

The asymmetric unit in plagionite (Table 2) contains sixteen atoms, all of which occupy a general position of the space group with the exception of Pb(3) and S(9), which occupy position 4 *e* 2. As in most Pb sulphosalts, the coordination of Pb is very irregular: Pb(1) has a distorted octahedral coordination with S neighbours at distances ranging from 2·74 to 3·16 Å (average: 2·97 Å); Pb(2) has six neighbours at distances between 2·83 and 3·17 Å (average: 2·97 Å) plus a seventh neighbour at 3·33 Å; Pb(3) has an irregular distribution of six neighbours at distances of 2·85 to 3·38 Å (average: 3·06 Å); two additional sulphurs at a much greater distance of 3·68 Å complete a square antiprismatic coordination for this atom. Three of the four Sb atoms have the [1+2+2] pyramidal coordination found for half of the Sb in stibnite, Sb_2S_3. Average distances for the three types of neighbours in the polyhedra are 2·47, 2·59 and 3·03 Å, respectively. The remaining Sb has a trigonal pyramidal coordination with an average bond length of 2·43 Å.

A projection along b of the polyhedra contained between $y=0$ and $y=1/2$ is presented in Fig. 1. The remainder of the cell content may be obtained when the depicted layer is shifted by the face-centring translation of the lattice, $\frac{1}{2}\frac{1}{2}0$. The most striking feature of the structure is the string of four Pb(1) and Pb(2) octahedra sharing edges along c. This cluster of octahedra is linked by the Pb(3) polyhedron to form a continuous chain parallel to $[10\bar{1}]$. The chain is flanked on either side by Sb pyramids. The strong short and intermediate bonds of each Sb square pyramid are directed toward the chain of Pb polyhedra. The long Pb(2)–S(9) bond and an Sb(3)–S(9)–Sb(3) bridge provide the only links between chains in (010). Two Pb(2) polyhedra in adjacent chains are further linked by corner sharing with a Pb(3) group immediately above the depicted layer, and also by a Pb(3) polyhedron below the layer.

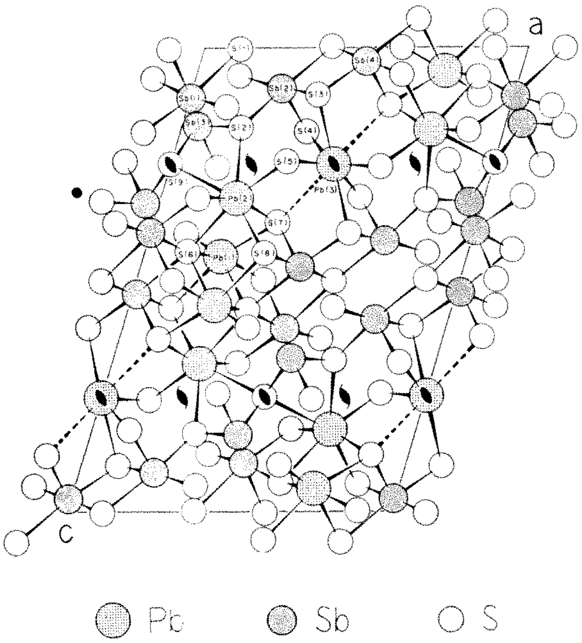

Fig. 1. Projection along *b* of the coordination polyhedra contained between $y = 0$ and $y = 1/2$ in plagionite. The *C* lattice provides an equivalent layer shifted ½½0 above the depicted polyhedra.

The arrangement of the Sb$^{[5]}$ polyhedra is another interesting feature. The bases of the square pyramids flanking each Pb chain are directed outwards from the chain and form a sheet parallel to (112). The Sb(1) and Sb(4) pyramids share an apical edge to form a limited chain similar to that in stibnite. In plagionite, however, this double chain shares an edge with the base of an Sb(2)$^{[5]}$ pyramid. A unit 6 polyhedra in width is thus formed rather than the quadruple chain found in stibnite. The opposed bases of Sb$^{[5]}$ pyramids on neighbouring Pb chains are parallel to (112). This feature explains the (112) cleavage observed in plagionite.

The characteristics of the structure of plagionite suggest a probable relation to other members of the group. Each successive member of the series contains an additional 8 Pb and 8 S per cell. This change in composition as well as the invariance of all lattice constants except *c* may be explained by adding one Pb and one S to a general position of the space group such that the number of Pb octahedra in the chain parallel to *c* increases by two. In accomplishing this, the array of Sb polyhedra may be left essentially unchanged. This would explain the common (112) cleavage in the family. Moreover, few additional bonds would be formed between Pb chains although the length of the chains is increased. This would account for the increasing ease of cleavage observed in the sequence plagionite–heteromorphite–semseyite. Inspection of Fig. 1, however, shows that the Sb polyhedra must be rearranged if the structure of fülöppite is to be derived by the removal of either Pb(1) or Pb(2) from the octahedral chain. This may explain the lack of cleavage in this mineral and the rather different value of β. Confirmation of this proposal must await completion of our structure determinations of the remaining minerals in the group.

Karman Vortices in the Flow of Drag-reducing Polymer Solutions

THE effect on flow properties of adding small quantities of soluble polymers, which are able to change turbulence and form solutions of a different structure, has been reviewed[1]. Aqueous solutions of polyethylene oxide exhibit viscoelastic properties immediately after the solute has dissolved, but these disappear on ageing. The solution, however, retains its capacity for reducing turbulent resistance of friction in flow near a smooth surface for a long time, although shear flow of the solution accelerates considerably the disappearance of this capacity. Aqueous solutions of the polymer Guar gum do not display continuum viscoelastic properties, but additions of it do reduce turbulent frictional resistance.

The reduction of this resistance is explained by the viscoelastic associates of the polymer macromolecules of the solution, which behave as liquid drops in a steady motion or as solid particles in a regime of rapidly changing velocity.

Although the continuum viscoelastic properties of the solution are not very significant for turbulent drag-reducing near a smooth surface, they have considerable influence on the development of inertial turbulent vortices (which depend slightly on velocity). The effect is opposite in sign to that shown by the viscoelastic associates. Polymer additives have been shown[2] to affect Karman vortices in the flow behind a body. The Karman vortices for the first approximation can be classified as inertial vortices because they appear at a certain Reynolds number and later depend only slightly on its value. Variations of vortex regime as compared with the Newtonian case can be expected for flows both of elastic and inelastic solutions of polymers, but the variations will differ in sign.

In our experiments a device was used which represented a wide vessel at the bottom of which a short convergent nozzle with an outlet diameter of 1 cm was fixed. A calibrated wire was fixed in the outlet cross-section of the nozzle. A thermoanemometer transducer was mounted behind the wire at a distance of 10 diameters from the wire. A thermoanemometer with a hot wedge transducer coated with quartz, produced by DISA Electronic, was used. The transducer was fixed in such a way that the hot film was perpendicular to the wire, so that all vortices separated from the wire flowed past the film. The vortices covered different parts of the hot film length, depending on the diameter of the wire. In the experiments, flow velocity around the wire was measured both by the volume method and by making use of the thermoanemometer. The frequency of the succession of vortices was determined by comparing Lissajous figures from oscillations on the oscillograph screen, as registered by the thermoanemometer, and those with known frequency yielded by an audio-frequency oscillator. The method used made it possible also to carry out comparative measurements of amplitudes of velocity pulsations in the area behind the wire. (Absolute measurements of

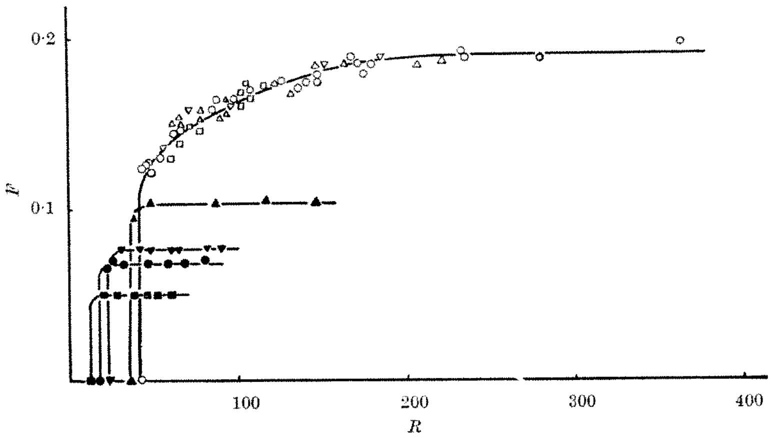

Fig. 1. Experimental results on the flow of water (open symbols) and polyethylene oxide solution (closed symbols) round wires of differing diameters: ●, 0·17 mm; ▲, 0·24 mm; ■, 0·31 mm; and ○, 0·57 mm. □■, 1; ○●, 2; ▽▼, 3; △▲, 4.

amplitudes were impossible owing to the considerable size of the transducer.)

The dimensionless frequency of the Karman vortex succession $F=fd/v$ is given in Fig. 1 as a function of the Reynolds number $R=vd/\nu$, where f is the frequency of the vortices, d is the wire diameter, v is the velocity of the liquid and ν is the kinematic viscosity coefficient. Experimental results shown by the open symbols were obtained from the flow of water around wires of various diameters. Data obtained for the flow of an aqueous solution of polyethylene oxide at a weight concentration of 10^{-4} are denoted by the closed symbols. The solution was kept for about four days after preparation; it preserved its continuum viscoelastic properties. It follows from the data given in Fig. 1 that the frequency of Karman vortices is lower for polyethylene oxide solutions than for the Newtonian liquid. The reduction in frequency is greater for smaller diameters of the wire. With decrease in wire diameter, the Reynolds number at which the first vortices appear also decreases. The vortex intensity in the flow of a viscoelastic solution of polyethylene oxide was found to be lower than that in the flow of water.

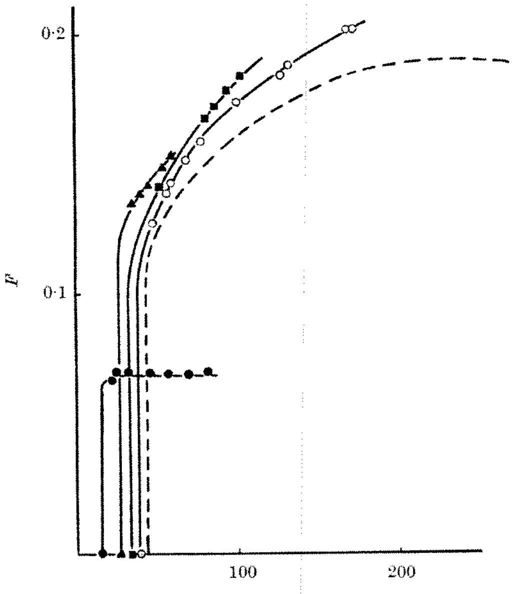

Fig. 2. The dimensionless frequency as a function of Reynolds number for the transition from elastic to inelastic polyethylene oxide solution (closed symbols) and for Guar gum (open symbols). ●, 1; ▲, 2; ■, 3; ○, 4.

In order to obtain an inelastic solution of polyethylene oxide containing associates, an elastic solution was passed through the centrifugal pump of a thermostat. Curves for the dimensionless frequency as a function of Reynolds number are given in Fig. 2, both for the transition of polyethylene oxide solution from elastic to inelastic associate-containing solution and for the subsequent breaking up of associates (closed symbols). The data were obtained for a solution of a concentration of 10^{-4} in the flow around a wire of 0·25 mm diameter. Curve 1 was obtained for an elastic solution, curves 2 and 3 for an inelastic one 30 and 60 min respectively after the associates were subject to the breaking up action of the pump vanes.

It follows from the data obtained that when a solution loses its viscoelastic properties, the frequency of the Karman vortex succession becomes at a certain moment somewhat higher than that in the Newtonian liquid (broken curve). A considerable increase in the amplitude of oscillations corresponding to the Karman vortices was observed, compared with the Newtonian case. With a further breaking up of associates the amplitude and frequency of oscillations decreased, tending to their values for water. An increase in the amplitude and frequency of oscillations was observed when the wire was in the flow of Guar gum solution. Data on the dimensionless frequency are given in Fig. 2 for Guar gum solution with a concentration of 5×10^{-4}, with a wire of 0·24 mm diameter (open symbols 4).

The data obtained are in good agreement with the theory that the intensity of inertial vortices increases in inelastic associate-containing solutions, while in elastic solutions it decreases. These data make the results obtained by Gadd[2] more precise.

We thank G. I. Barenblatt for helpful discussions and L. A. Rodionova for assistance in carrying out the experiments.

Effect of Rotational Phase Transformations on Dry (Coulomb) Friction

ONE of the more peculiar of the solid-state crystalline phase transformations which occur in nature is that in which a highly ordered crystalline phase is exchanged for one exhibiting a large degree of rotational disorder. In such a transformation some weaker bonds are broken while stronger bonds remain. Parts of a molecule are then free to rotate about the fixed structure. For each of the two phases it is not uncommon to find considerably different values in interfacial tension at the crystal–melt interface. For carbon tetrachloride, one of the many substances exhibiting a rotational disordered phase, this interfacial tension decreases from 13·9 erg/cm² for the more ordered phase to 6·67 erg/cm² for the rotationally disordered phase[1].

In regard to Coulomb type (dry) friction, both the lowering of surface tension and/or the rotational freedom may be expected to produce dramatic changes. For example, rotational freedom on a molecular scale may be kinematically favourable to the sliding process. On the other hand, surface energy has long been thought to play an important part in friction and wear processes[2]. It is also notable that the experimental work to be described produces results consistent with these expectations.

The sliding system chosen for investigation was that of a hard steel hemisphere sliding on solid state CCl_4. CCl_4 was chosen from all those known to exhibit the previously described phase transformation for the following reasons. (i) The temperature (222·5 K) (ref. 3) at which it transforms is easily attainable in practice. (ii) The transformation temperature is sufficiently removed from its melting point (250·3 K) (ref. 3) to avoid any ambiguity in the experimental observations. (iii) Pure CCl_4 is easily obtainable.

Fig. 1 shows the simple experimental apparatus used. A dual walled (vacuum/liquid nitrogen) container houses the experimental elements. Initially an annular vessel (C) containing liquid CCl_4 is inverted on a glass plate and lowered into the container. The glass plate produces a smooth surface of CCl_4 on freezing. Introduction of liquid nitrogen in the container wall lowers the interior temperature to about 190 K. The glass plate is removed and the vessel of frozen CCl_4 is righted and fastened to the bottom end of a driveshaft as shown in the diagram. A steel hemisphere mounted on the end of a strain-gauged beam rests on the CCl_4 surface under a normal load of 110 g applied by a pulley-hung weight (W). The driveshaft is given several rotations clockwise and counterclockwise, to ensure a uniform grooved depression (nearly invisible to the naked eye). The apparatus is kept moisture free by a flow of dried argon. The experiment starts when the flow of liquid nitrogen is halted, which occurs when the interior temperature is about 180 K. As the interior temperature drifts slowly back towards room temperature a thermocouple, frozen into the CCl_4 surface, gives readings of the temperature. Friction forces generated by the constant to and fro motion of the driveshaft, which has an average sliding velocity of 4·3 cm s^{-1}, are recorded from the strain gauges. When the phase transformation temperature (222·5 K) is attained a timewise sequence of relatively constant temperatures is noted as the change of phase proceeds. The results of interest are shown in Fig. 2 as a plot of normalized friction force against CCl_4 surface temperature. The magnitude of the maximum friction force corresponding to an ordinate value of 1·0 on this graph is 9·4 g, giving a maximum coefficient of friction of 0·085. The main feature of interest is that exactly at the transition temperature the forces of friction fall to less than half their previous values. (No surface changes visible to the naked eye occur until melting.) Of course, a second drop in friction occurs as the melting temperature is attained.

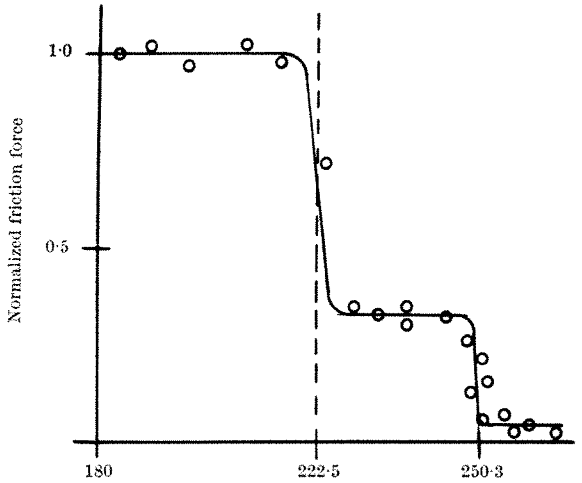

Fig. 2. Experimental results showing a decrease in friction at the transition temperature.

It may also be noted that these observations are reversible, that is, if at, say, 230 K the flow of liquid nitrogen is reinstated, then at 222·5 K, the phase transformation temperature, friction values will abruptly rise.

Further work is planned using a "plastic" crystal, carbon tetrabromide, in place of carbon tetrachloride. The interesting features of CBr_4 are (i) its surface tension values of 10·7 erg/cm^2 and 21·8 erg/cm^2 (ref. 1) for the disordered and ordered phases respectively, and (ii) the fact that its ability to rotate is hindered. This may make it possible to discern which property contributes to the lowering of friction, that is, the onset of rotational disorder or the lowering surface tension.

Friction Reduction Characteristics of Fibrous and Colloidal Substances

THE phenomenon of friction reduction produced in smooth pipes by fibre suspensions in turbulent flow has been observed by several investigators over the past three decades, particularly by those examining the flow characteristics of wood-pulp fibre suspensions[1]. During a recent study of the friction-reducing properties of long-chain, water-soluble polymer molecules, an investigation was made to determine whether certain water-insoluble fibrous materials, or colloidal materials other than wood-pulp fibres, would also produce a friction-reduction effect. The measurements were made by means of a rheometer with a steel capillary tube 0·046 inches in diameter. Transducers mounted 5 inches apart along the capillary tube were used to measure the pressure drop. The sample was forced through the capillary by means of a constant-speed,

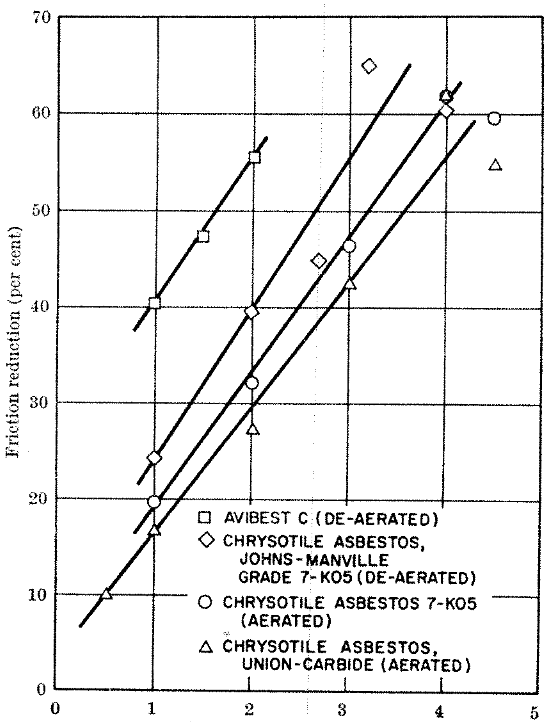

Fig. 1. Friction reduction of asbestos materials.

motor-driven plunger at a rate of approximately 13 cm³ per second. Friction reduction (FR) was computed as follows

$$\text{per cent FR} = 100\left(1 - \frac{\Delta P_2}{\Delta P_1}\right)$$

where ΔP_1 = pressure drop using water or other reference liquid alone, ΔP_2 = pressure drop using sample dispersion.

The measurements were made at room temperature (24° C). The dispersions were prepared by agitating the sample and the reference liquid for 5 min in a high-shear type blender at 21,000 r.p.m.

The first fibrous material selected for study, the natural inorganic polymer 'Chrysotile' asbestos (Johns-Manville grade 7*K*05), produced noteworthy results. A maximum friction reduction of 65 per cent was achieved at an asbestos concentration of 3·2 weight per cent. The *p*H of the dispersion was adjusted to between 4 and 4·5 with acetic acid before agitation in the blender. Deaerated dispersions proved to be more effective than aerated ones.

A recently developed microcrystalline product derived from 'Chrysotile' asbestos, 'Avibest C' (FMC Corporation), was also tested. This material has a rod-like particle shape, with a maximum particle dimension of 0·5 micron. It was surmised that 'Avibest C' would be more effective on a weight basis than 'Chrysotile' asbestos in reducing friction because of its smaller particle size. The results confirmed this belief (Fig. 1).

Other novel microcrystalline colloidal materials manufactured by the FMC Corporation were subsequently evaluated, and the results are shown in Fig. 2. 'Avitene H', an acid salt derived from a bovine hide collagen, produced a maximum friction reduction of 51·7 per cent at a concentration of 0·125 per cent. Its particle shape appears to be spheroidal[2]. 'Avicel CM' (later renamed 'Aviloid'), a cellulose product with a fibre-like particle shape, produced a maximum friction reduction of 47 per cent at a concentration of 1·5 per cent. The same concentration of 'Avamide-6', a microcrystalline nylon, did not reduce friction.

The materials that produced friction reduction varied in their properties according to production lot and period of ageing. For example, a new sample of 'Avicel CM' that produced a friction reduction of 47 per cent at a concentration of 1·5 per cent yielded only a 31 per cent reduction after 1·5 yr of ageing. 'Avibest C' gave more consistent results, even after ageing for the same period. The increasing stiffness of the gels formed by 'Avibest' and 'Avicel' dispersions at concentrations greater than 2 per cent made them too difficult to test in the narrow-capillary rheometer described here.

A variety of other water-insoluble materials that have either fibre-like or colloidal-size particles (or, in some cases, both) were evaluated for friction-reduction capability. The results are presented in Table 1.

Table 1. FRICTION CHARACTERISTICS OF FIBROUS AND COLLOIDAL DISPERSIONS IN TURBULENT FLOW (IN WATER, EXCEPT 'AVIBEST C')

Substance	Concentration (weight per cent)	Friction change Reduction (per cent)	Friction change Increase (per cent)	Maximum particle dimension (μm)
'Baymal' colloidal alumina (DuPont)	1·0		1·4	0·1
	3·0		4·6	
'Attagel 20'	2·0		4·0	0·14
Attapulgus clay	2·5		5·4	(average equivalent spherical diameter)
'Benaqua', clay product (National Lead Co.)	0·1	0·2		0·1
	1·0	10·2		
	1·5	13·4		
'Aquablak K' colloidal carbon	0·3		1·1	
	1·0		2·4	
Pigmentary potassium titanate	3·0	0·0		10·0
'Avibest C' in Dow-Corning 200 silicone fluid (1 cstk)	1·0	12·1		0·5
'Avibest C' in tetrahydrofurfuryl alcohol	0·5		5·7	0·5
	1·5		24·4	

Particles of colloidal alumina, although similar in size and shape to those of the microcrystalline cellulose developed by FMC[3], produced an increase of friction. The increase was greater at *p*H 8 than at *p*H 4. 'Attagel 20' and pigmentary potassium titanate, which have needle-like particles, failed to produce friction reduction. Benaqua, a magnesium silicate clay with a platelet particle form, produced a 13·4 per cent friction reduction at a concentration of 1·5 per cent. Above 1·5 per cent, the gel was too thick for testing in the rheometer. 'Avibest C', in Dow-Corning 200 silicone fluid, produced a 12 per cent friction reduction. A considerable increase in friction was obtained, however, with a dispersion of 'Avibest C' in tetrahydrofurfuryl alcohol.

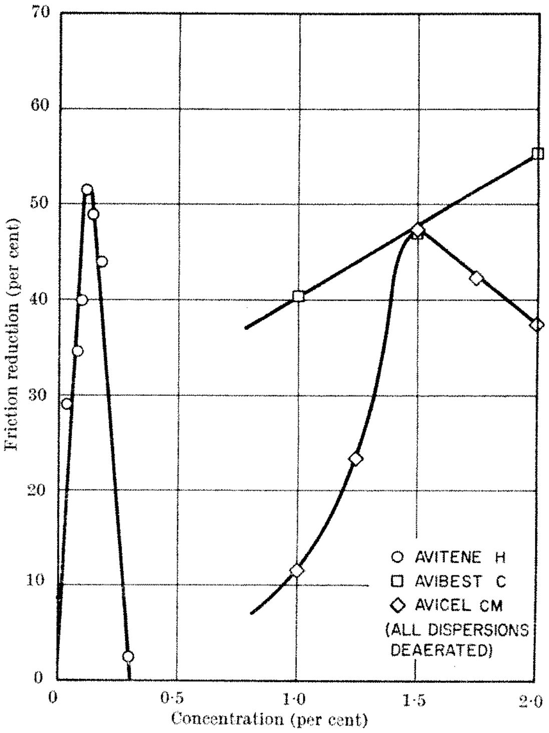

Fig. 2. Friction reduction of microcrystalline substances.

No data are available to explain the ability of some fibre-like substances to reduce friction, while others of a similar particle size and shape are unable to do so. It can only be hypothesized that the explanation lies in the types of chemical groups that exist on the surfaces of the particles, or in variations in particle flexibility. The vastly different results obtained with 'Avibest C' dispersions in different liquids are likewise not understood. A clearer, although not necessarily complete, understanding will be obtained when tests are performed with a number of other organic liquids.

BIOLOGICAL SCIENCES

ATPase Activity of the Sodium Pump needs Phosphatidylserine

IT has frequently been suggested that the chemical properties of phospholipids and their prevalence in cell membranes make them particularly suitable compounds to serve as carrier molecules for the transport of cations. Some support for this suggestion has been provided by studies of the cation binding properties of phospholipids[1,2] and of various model systems involving phospholipids[3-5]. Taken together, these investigations indicated that some phospholipids might be especially concerned in the active transport of Na^+ and K^+, but the evidence is not conclusive. The concept of such a carrier for ion transport antedates the work showing the involvement of ATP and its enzymatic hydrolysis in the Na^+ pump; and during the past decade there has been a shift of interest and emphasis towards the role of the membrane ATPase system in active cation transport[6]. During this period, however, evidence has accumulated that the Na^+, K^+-activated ATPase is eliminated when lipids are removed from membranes by solvent extraction, treatment with detergents, or exposure to phospholipases[7-9]. The question therefore arises whether phospholipid might provide a carrier system in which the protein of the ATPase is also involved, such that the ATPase activity depends on lipid as well as protein.

There have been several reports of the activation of ATPases by addition of lipid after the enzyme preparations had been treated with deoxycholate or phospholipase, but there is no agreement on the nature of the lipid and whether the ATPase activity is that of the Na^+ pump. For example, although activation by lecithin has been reported by some workers[10,11], others have failed to confirm this action[7,12], or have obtained equivocal results[13]. In one report, phosphatidylserine was shown to activate but not lecithin[12]. Again, activation by a number of different lipids has been claimed but not always confirmed[10,12,14-17]. In view of the previous chemical work implicating phospholipids as potential carrier substances, we have investigated the phospholipid requirement for the ATPase of the Na^+ pump.

Solubilization of a membrane-containing fraction (microsomal) from ox brain cortex with deoxycholate[11] removed most or all of the ouabain inhibited ATPase activity. *p*-Nitrophenylphosphatase activity, which is associated with the ATPase, was also reduced in the same way. Both these enzymatic activities were restored after adding sonicated dispersions of crude commercial samples of phosphatidic acid, phosphatidylinositol or phosphatidylserine but not phosphatidylethanolamine or phosphatidylcholine (lecithin). The commercial samples were impure, however, and, after they had been partially purified by thin-layer chromatography, definite activation was demonstrated only with that component of the crude samples which migrated like phosphatidylserine.

The action of this lipid has been investigated in detail. With a typical enzyme preparation, ouabain sensitive ATPase activity (in µmoles P_i liberated per g protein per min) was raised ten-fold, from 13 to 127. This difference was found only when the incubation medium contained both Na^+ and K^+, because in their absence phosphatidylserine did not stimulate. This shows that the activity dependent on phosphatidylserine was that part of the ATPase requiring Na^+ and K^+, and which is completely inhibited by ouabain. Another inhibitor which largely opposes the action of Na^+ and K^+ is oligomycin and this compound decreased the ATPase activity dependent on phosphatidylserine from 158 to 68. *p*-Nitrophenylphosphatase activity (in µmoles *p*-nitrophenol liberated per g protein per min) was also stimulated by phosphatidylserine. Sensitivity to ouabain was only 4 without phosphatidylserine but 21 after adding the lipid. By contrast with ATP hydrolysis, this activity was little affected by oligomycin. The enzymatic activity dependent on phosphatidylserine therefore exhibited properties characteristic of the ATPase of the Na^+ pump. It seems that this activity can be markedly reduced by treatment with a detergent.

A test was made to see if ouabain-sensitive ATPase activity was raised by phosphatidylserine in the ordinary enzyme preparation before it had been treated with deoxycholate. An increase from 77 to 170 was found with this lipid, thus raising the proportion of ouabain sensitive activity from 38 to 55 per cent. This result suggests that phospholipid may be lost during preparation of the membrane fraction.

The results have a bearing on two aspects of membrane phenomena. First, there is the requirement for phosphatidylserine for optimum activity of an enzyme which is membrane bound. The question of whether ouabain sensitive ATPase and *p*-nitrophenylphosphatase activity both reside in the same catalytic unit is not at present resolved[13,15,17], but it is nevertheless clear from our results that both activities depend on phosphatidylserine. Very few enzymes have been shown to require phospholipid for their activity and, indeed, characterization of enzymes usually involves purification to a greater or lesser extent, and ideally a crystalline protein is examined. The activation of ATPase and *p*-nitrophenylphosphatase by phosphatidylserine, and by none of the other four phospholipids which we have examined, suggests a requirement for a specific phospholipid. From the point of view of enzyme action, therefore, it seems that those properties which make the membrane bound ATPase of great interest physiologically are dependent not just on protein but on protein and lipid together. Characterization of the Na^+-activated ATPase as a chemical entity therefore presents a much more formidable problem than characterization in the classical sense, in which an enzyme consists solely of protein. The other aspect of our results relates to the functional consequence of ATPase activity which is the active transport of Na^+ and K^+ across the cell membrane. It seems likely that the carrier substance for the transport of these ions is a complex unit of phosphatidylserine and protein. The inhibition of transport by ouabain may arise from interference with the interaction between protein and phosphatidylserine. Other obvious implications of our results concern the micro-architecture of the cell membrane in which phosphatidylserine perhaps maintains the appropriate orientation of the protein molecule so that catalysis of ATP is associated with the transport of ions.

Active Ionic Transport across Biological Membranes: Possible Role of Electrons and Protons

THE conversion of metabolic energy into useful work is a very efficient process in biological cells. The energy in ATP is transformed into mechanical, electrical and osmotic work at efficiencies which have been calculated to approach 100 per cent for acid secretion in the stomach[1], active Na^+ transport in frog skin[2] and sartorius muscle contraction[3]. These observations show that energy is converted in biological cells by a process which is not limited by a Carnot efficiency factor (about 2 per cent in warm blooded animals). The process could involve electrochemical "cold" combustion, in which chemical energy is transformed into electronic potential energy, in much the same way as the operation of a fuel cell[4]. Accordingly, Mitchell[5,6] likened the oxido/reduction and phosphorylation processes in his chemiosmotic hypothesis to a protonic fuel cell in which ATP synthesis was construed as a vectorial reaction driven by a "proton-motive" force across the mitochondrial membrane.

There is evidence[7] for such an electrochemical mechanism of energy conversion from metabolic energy to osmotic work (active transport) across certain biological membranes. (The mechanism can also be called electrodic: Bockris and Conway[8] define "electrodics" as "the study of processes which occur at the surface of an electronic conductor in contact with a liquid".) The evidence comes from the unique character of the non-linearity in the voltage-current characteristics displayed by live secretory tissues, in contrast to the linear relationship of dead tissue. When these characteristics are plotted as voltage against the logarithm of the current (Fig. 1), they display straight line relationships at displacements from resting potential larger than 40–50 mV. Using the theory of rate processes[9], the relationship at high voltage can be expressed as

$$i = i_0 \exp\left[\frac{(1-\beta)\ V^* F}{RT}\right]$$

where i_0 is the exchange current density (a constant), F is the Faraday, R is the gas constant, T is the absolute temperature, V^* is the displacement from resting potential and β is the symmetry factor. β has been calculated, from the magnitude of the slopes of a variety of tissues, to be close to 0·5, as shown in Table 1. The range of β values encountered experimentally is 0·35 to 0·70, representing the normal type of asymmetry accompanying uniquely determinable processes (from the β values) such as the present one, which is characterized by a single, almost symmetrical, rate-determining energy barrier[9–12]. The most likely process showing the voltage-current characteristics of Fig. 1 is an electrodic one in which the rate-determining step would be the passage of electrons between one of the solutions and an electron conductor in the membrane[13]. Electronic rate-determining steps of this type have been studied extensively at metal-solution[14] and semiconductor-solution[15] interfaces. The latter case is probably representative of the conditions in biological cells[16].

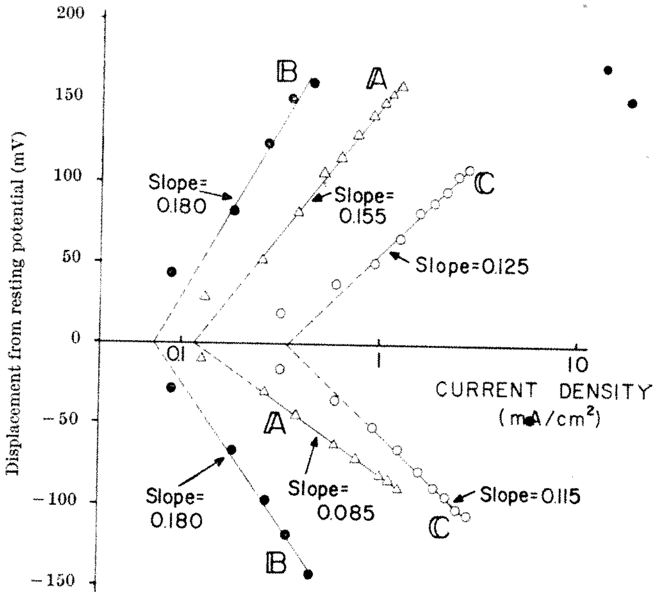

Fig. 1. Displacement from resting potential versus logarithm of current density for (*A*) frog gastric mucosa, (*B*) frog skin and (*C*) perch swimbladder.

Table 1. VALUES OF β CALCULATED FROM DATA ON SECRETORY TISSUES AND NERVE CELLS

Animal species and membrane type	Exponential slope in mV	Calculated value of β	Source of data
Frog gastric mucosa	125	0·52	(8)
Frog skin	180	0·67	(8)
Perch swimbladder	115	0·48	(8)
Rabbit oviduct	145	0·49	(25)
Loligo axon	110	0·45	(26)
Sepia axon	90	0·33	(27)
Lobster axon	155	0·61	(28)
Frog node	105	0·43	(29)

The electrons crossing one of the membrane-solution interfaces would take part in a redox reaction at the interface, in which a hydrogen atom is desorbed from the membrane to form a hydronium ion in the solution for each electron transferred to the electronic conductor in the membrane. The opposite would be the case for an electron which transferred from the electron conductor to one of the solutions. The complete model for electrodic current passage across the membrane is shown in Fig. 2, where it can be seen that for every electron which crosses the membrane in one direction, a proton traverses the full span from solution to solution.

This model has been derived strictly from the voltage-current characteristic of secretory tissue, yet it bears a very close resemblance to the protonic fuel cell described by Mitchell[5,6]. Because one of the properties of this electronic and protonic pathway is its dependence on intact metabolism[7], and because ATPases seem to be present in these tissues[17,18], specific models of secretory

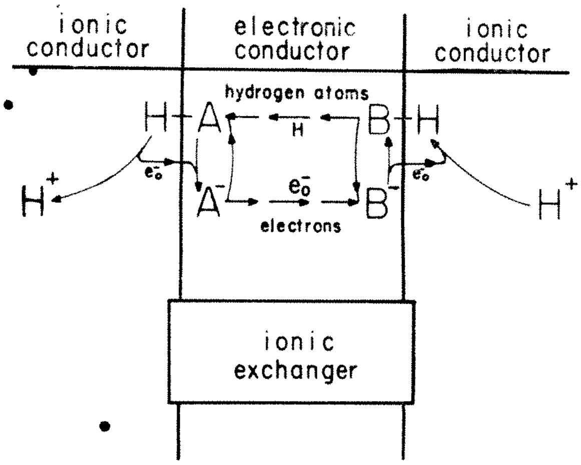

Fig. 2. Model for electrodic current passage through a membrane.

cells can be proposed on the assumption that the pathway actually is a reversible chemiosmotic-like ATPase, located at the secretory membrane and with the electrodic current flowing through it. ATP hydrolysis in such a vectorially oriented process could constitute a case of heterogeneous catalysis[14] involving redox reactions with electron transfers, which would result in the net transfer of H^+ ions across the membrane[5,6]. The local *p*H gradient created in this manner could cause active transfer of ions in a specialized ion-exchange structure with *p*H-dependent selectivity.

In the gastric mucosa, this ion-exchange structure could allow selectively for Cl^- ion movement by ion pair formation with the H^+ ions transported in the ATPase, resulting in the observed acid secretion[19].

In frog skin, this structure would favour Na^+ ions at the high *p*H side and K^+ and H^+ ions at the low *p*H side[20]. The Na^+ ions inside the cell would adsorb on the exchanger, traverse the membrane to the low *p*H side where the opposite selectivity exists, and exchange for K^+ or H^+ ions which would travel to the other side to maintain electroneutrality. The local *p*H gradient produced by the ATPase would thus provide the driving force for active Na^+ transport. Active transport of other ions and varying respiratory quotients could be modelled from the basic chemiosmotic ATPases, by assuming differentiated ion-exchange structures which result in the specialized active transport properties of various tissues. The resulting electrodic models of active ionic transport are found not only to be consistent with a variety of experimental observations, but also to provide novel interpretations for many observed phenomena such as the origin of the tissue potential difference, the nature of exchange diffusion, the actions of various drugs and many other properties[21].

Electrodic processes may be present in aspects of cellular function other than those related to the direct conversion of metabolic energy into useful work. One such example may be nerve excitation, for the steady state voltage-current characteristics of nerve (K^+ current as function of clamping voltage) are very similar in the depolarizing direction to those of secretory cells. After the series resistance inherent in the uncompensated feedback type of measurement[22] is subtracted from the original data, the voltage-current characteristics of nerves from a variety of species are described by equation 1 at V^* larger than 40–50 mV. The values of β obtained from these curves (Table 1) fall within the same range as those from secretory tissues, hinting at the possibility that electrodic processes may occur in nerve as well.

An electrodic model of nerve excitation can be proposed, based on a mechanism similar to that discussed for secretory tissue, but not metabolically dependent. The quantitative dependence of the K^+ current on applied potential[23] is modelled by a two step process which involves the primary transport of H^+ ions (electrodic current) and the secondary exchange of the H^+ ions for K^+ ions, resulting in the observed K^+ current. No specific assumptions need be made about the process of Na^+ activation in this model; the inactivation of Na^+, however, is assumed to occur through the lowering of the local external *p*H by protonic transport across the membrane. The excess H^+ ions could react with the negative membrane sites to prevent the passage of the Na^+ current as was suggested by Hille[24] for frog node of Ranvier. The reaction of H^+ ions with the membrane sites would prevent the H^+ ions from being immediately exchanged for K^+ ions from the nerve cytoplasm, and thus produce the observed delay in the rise of K^+ current to its steady-state value. This model qualitatively accounts for a variety of observations made on nerve, including the results of voltage-clamp experiments, effects of varying ionic concentrations on the bathing solutions and the action of various drugs on nerve excitation[21].

I thank Drs R. E. Davies and J. O'M. Bockris for their advice and encouragement. Support came from the US Public Health Service.

Discreteness of Conductance Change in Bimolecular Lipid Membranes in the Presence of Certain Antibiotics

NET ion movements across biological or synthetic lipid membranes may take place by various mechanisms, underlying all of which there is a rather ill-defined and small ion leakage or background conductance. Most ions

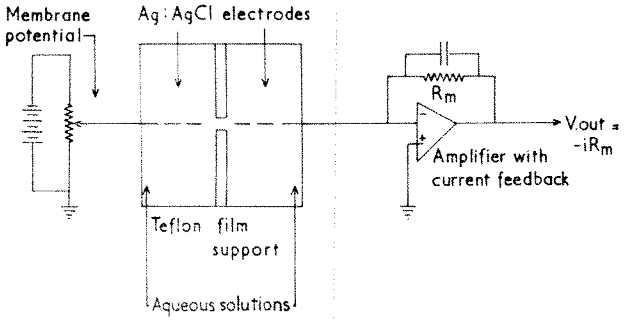

Fig. 1. Schematic diagram of the apparatus used to measure conductance.

permeate by means of pathways involving either permanent or transient modifications of the basic structure of the membrane. If permanent pathways are involved, a given membrane conductance may be accounted for by routes which are either numerous and of low conductance or few and of high conductance. For transient pathways, duration must also be considered. Thus, if a carrier is invoked, the duration will be the time the carrier, complexed with an ion, spends shuttling across the membrane. For a pore, the duration is the time for which it remains open to ions. At present little is known concerning the number, conductance and duration of the ionic pathways in any membrane of the types mentioned. Limited information is available for the nerve membrane, although this is rather imprecise and indirect[1].

The artificial bimolecular lipid film is an almost ideal structure in which to study single conductance pathways. There are many substances which render these model membranes highly permeable to ions although we know of only one publication giving evidence of discrete conductance pathways[2]. This was for a poorly characterized proteinaceous material[3]; the magnitude of the unit conductance change was about $10^{-10}\ \Omega^{-1}$. The conductance of a carefully prepared bimolecular lipid film is so low that in certain circumstances it should be possible to detect the conduction corresponding to a single molecule of a permeability-inducing substance even if this is considerably less than $10^{-10}\ \Omega^{-1}$. In this study the antibiotics nonactin, nystatin and gramicidin A were examined from this standpoint.

Films were formed from solutions of lecithin or glycerol mono-oleate in *n*-decane, in a hole on a Fluon support, by the injection manometer method[4]. For systems containing nystatin, however, cholesterol was also added. Conductance was measured by applying a known potential (normally 100 mV) to one side of the film and recording the current necessary to maintain the other side at zero (Fig. 1). Much care was required to isolate the apparatus adequately from mechanical and electrical noise. The time resolution of conductance fluctuations depended on the magnitude of the fluctuation. Transient increases in conductance of $5 \times 10^{-13}\ \Omega^{-1}$ could be observed, provided they lasted for about 100 ms. The corresponding resolution at higher conductances was 10 ms at $2 \times 10^{-11}\ \Omega^{-1}$ and 1 ms at $10^{-10}\ \Omega^{-1}$.

In the absence of antibiotic, the conductance of the black films was constant within the resolution of the apparatus. When antibiotic molecules were present the conductance increased, as has previously been noted[5-7,10]. At very low levels of conductance the manner of the increase depended markedly on the nature of the antibiotic. With nonactin the conductance increased smoothly on the formation of a black film. No step changes were observed down to a level of $5 \times 10^{-13}\ \Omega^{-1}$, but because of the resolution of the apparatus any step this small which was reversed in less than about 100 ms would not have been seen. For nystatin (reproducible) fluctuations in the conductance were also absent, the largest possible step being $2 \times 10^{-13}\ \Omega^{-1}$. Again no transient decreases in conductance were observed.

By contrast, when the films contained gramicidin A in low concentrations the conductance fluctuated with time in a well defined step-like fashion (Fig. 2). At high concentrations the steps overlap to give a high conductance in which the fluctuations can no longer be resolved. The step heights at first glance appear uniform, but in fact have a distribution of sizes which, in 1·0 M NaCl, has a peak at approximately $2{\cdot}4 \times 10^{-11}\ \Omega^{-1}$. The effects of electrolyte concentration and applied potential on the step height which corresponds to the distribution peak are shown in Figs. 3 and 4, respectively. The frequency of occurrence of steps increases with applied potential.

Nonactin forms 1 : 1 complexes with univalent ions[8], and it has been suggested that the macrocyclic molecule carries ions across the membrane[9]. The present findings neither contradict nor support this mechanism. The absence of steps for nystatin is interesting, for it has been inferred that the nystatin aggregates in the film to form pores of approximately 8 Å in diameter[11]. If such pores are considered to be right cylinders filled with electrolyte solution, it is very unlikely that they would have conductances of less than $2 \times 10^{-13}\ \Omega^{-1}$. The fact that conductance changes greater than this were not detected indicates that if pores exist they remain open for less than 100 ms.

Gramicidin A is nearly twice the size of either nonactin or nystatin, a fact which may help to explain the pronounced unit conductance changes it produces. In saturated NaCl and for 100 mV applied potential the net transfer of charge per conducting channel corresponds to 2×10^7 ions/s. This suggests that the effective ionic mobility across the membrane is little less than for the inorganic ion in water, and consequently a pore, rather than a carrier mechanism, is indicated. The commencement and termination of a step might correspond to the arrival in, and departure from, the film of a gramicidin molecule. There is, however, evidence against this mechanism. Another possible explanation arises from the suggestion that dimers of gramicidin may be the conducting unit in the black film[6]: commencement and termination of a step could correspond to the formation and dis-

Genetic Curing of Blindness in *Phycomyces blakesleeanus*: a Quantitative Assessment of Dominance

Delbrück and Reichardt[1] have pointed out the possible potential of *Phycomyces* as an organism for investigating mechanisms of sensory perception. This fungus produces single-celled sporangiophores which are sensitive to light, gravity and stretch. It also shows an avoidance response which is a proclivity to grow away from solid objects. Either tropic responses or changes in rates of growth are produced.

By way of an attempt to identify the receptor pigment involved in light-responses, I have thought of the following possibility. Using a suitable non-phototropic mutant, and assuming that the "visual" defect is due to a lack of photopigment, suitable solutions which might contain the pigment or its messenger RNA (for example, purified fractions from extracts of the wild type fungus) might be used to try to restore the response to light. Such non-nuclear or biochemical "curing" of the visual defect would constitute a biological assay for the receptor or a precursor. At present there is no suitable assay for the photopigment. However, before trying biochemical restoration of vision it is essential to test whether a defect in response to light can be cured genetically. The likelihood of success with biochemical curing would tend to be greater if, when wild type nuclei were added to the photomutant, the resulting improvement in vision were large. Experiments to determine quantitatively the extent of genetic curing are reported here.

Strain C2, genotype *car-5*(−), a mutant which forms white sporangia and differs from the wild type in the synthesis of β-carotene[2] but not in its light-sensitivity, was mutagenized again using N-methyl-N′-nitro-N-nitrosoguanidine[3] at a concentration of 0·1 mg/ml. in 6·5 mM citrate/sodium phosphate buffer, *p*H 7·0. Agar plates were seeded with mutagenized spores. Photomutants were selected by Heisenberg's[4] technique, that is, I took those that grew upwards in a glass-bottomed box illuminated from below. These mutants are not entirely unresponsive to light but have a threshold of intensity higher than the wild type, that is, they tend to be "night-blind". They show some responses characteristic of the wild type—geotropism and avoidance. Although the poorer sensitivity to light might result from a dearth of receptor pigment, other possibilities (for example, a modified receptor pigment, a change in the process of transduction or a modified mechanism of dark adaptation) cannot be excluded.

From measurements of threshold intensity for light-perception using the technique of Varjù *et al.*[5], a photomutant (strain C146, genotype *car-5 mad-117*(−)) having a threshold corresponding to an intensity several hundred times greater than that for the wild type was chosen for attempts to improve its sight. For experiments of this kind, a technique had to be devised to ensure that sufficient donor material entered the cell and was transported into a newly sprouted sporangiophore. A simple, efficient micro-injection technique was devised for transferring cell-sap from one sporangiophore to another. A red mutant (strain C9, genotype *car R21*(−)) which accumulates lycopene due to a block in the cyclization step of β-carotene biosynthesis[2], was used as a donor. This mutant is fully photosensitive. Sporangiophores of the recipient mutant were used at a stage before the sporangium had formed. About 12 h after injection a new sporangiophore sprouted from the apical end and formed a yellow sporangium. Plated spores from such sporangia produced colonies of white, red and various shades of yellow. The latter are heterokaryons and were used for determining a quantitative relationship between threshold intensity and nuclear proportion. Mycelia of several shades of yellow were used. Samples of mycelia about 10 mm² were transferred to plastic plates containing glucose, asparagine and yeast, all solidified by agar[3], and

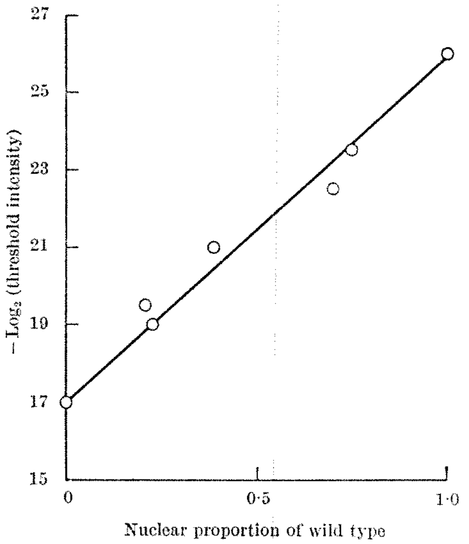

Fig. 1. $-\mathrm{Log}_2$ (threshold intensity) plotted against nuclear proportion. Curve shows restoration of vision using a heterokaryon made from a fully photosensitive red mutant and a white, night-blind mutant.

allowed to produce sporangia. Spores corresponding to each shade of yellow mycelium were collected and kept for the determination of nuclear proportion. Heisenberg and Cerdá-Olmedo[3] have shown that the nuclear ratio is constant in all parts of the mycelium, sporangiophores and sporangia and that random samples of nuclei are packaged into spores. Their technique was used here for determining the proportions of red (phototropic) and white (relatively non-phototropic) nuclei in each selected yellow mycelium.

Thresholds for light-perception corresponding to each nuclear proportion were then determined. Pieces (10 mm^2 approximately) of young mycelia from each of the chosen yellows were placed in vials each containing 1·5 ml. of growth medium (potato–dextrose–agar and 1 ml./l. of 0·05 per cent (w/v) thiamine). After 24 h many frail sporangiophores appeared, followed usually after 5 days by several sturdy sporangiophores. To prevent the production of frail sporangiophores the sample of mycelium was plated on growth medium in plastic dishes and young, robust sporangiophores were transferred individually to vials of medium for the determination of threshold after further growth.

Fig. 1 shows the effect of nuclear proportion on $-\log_2$ (threshold intensity). The latter quantity, based on a scale defined by Delbrück and Reichardt[1], may be expected to increase with the concentration or "effectiveness" of the photoreceptor pigment. The experimental variability is $\log_2$ intensity $= \pm 1$ approximately. From these results it seems that, although there is a considerable dominance of the photomutant, there is indeed curing of night-blindness by the admixture of wild type nuclei. If the data in Fig. 1 follow an exponential relationship, it might be conjectured that a missense mutation of a structural gene is involved, giving rise to an altered polypeptide subunit (for example, ref. 6) which associates with other subunits in an oligomeric form. Only the homo-oligomer of the wild type subunit would constitute the active photoreceptor. But this is one of many possibilities.

Cerdá-Olmedo has suggested (personal communication) that from a plot of threshold against nuclear proportion, as determined in this work, photomutants be classified by the value of the ordinate at $P = 0·5$. For strain C146 the value of the ordinate at a nuclear ratio of 0·5 is 21·5. High values for this parameter would obviously denote dominance of the wild type. This remains to be investigated.

Further evidence for the genetic curing of night-blindness was found by making the heterokaryon, C5 * C146, using the microsurgical technique mentioned here. C5 (genotype *car-10*(−)) is similar to C2 in that it forms white sporangia and differs from the wild type in its synthesis of β-carotene[2]. Sporangiophores from the resulting yellow heterokaryotic mycellia again showed an improved response to light. Because of the absence of the red colour-marker, a detailed quantitative examination was not made.

That blindness can be cured genetically is encouraging for work on possible biochemical restoration of vision. The simplicity and reliability of the micro-injection technique itself lead to further opportunities for studying the genetics and development of *Phycomyces*. For example, a quantitative analysis of the type shown here is necessary for any extensive investigation of complementation between photomutants.

I thank Professor Max Delbrück for his encouragement and Dr E. Cerdá-Olmedo for his help. This work was supported by the Gosney Fund of the California Institute of Technology and by the Council for Scientific and Industrial Research, Pretoria.

Anti-trachoma Activity of Rifampicin and Rifamycin SV Derivatives

RIFAMPICIN effectively inhibits the replication of trachoma agents both in infected cell cultures *in vitro*[1] and in embryonated eggs *in vivo*[2]. It acts during the initial developmental stages, characterized by active RNA synthesis[3]. The anti-trachoma inhibitory effect of rifampicin exceeded that of rifamycin SV[1,2], indicating that the presence of a hydrazone sidechain in carbon 3 of the chromophoric part of rifamycin SV might be concerned in the activity. To determine the function of the side chain, we have compared the effect of four compounds synthesized by adding to the formyl-rifamycin derivative of rifamycin SV different side chains at carbon 3. We have found that the presence of a hydrazone side chain in the rifamycin SV molecule enhanced the anti-trachoma activity of the drug *in vitro* and was essential for the inhibition of trachoma agent *in vivo*.

We used the T'ang strain of trachoma agent (TRIC// RC–PK/PK–2/OT) for the *in vitro* studies. For the *in vivo* studies we have also used the Bour strain (TRIC//USA–Cal, CAL–1/OT) of trachoma agent and the 6BC strain of psittacosis agent. The agents were propagated and titrated in cell cultures and embryonated eggs as previously reported[1,2].

The compounds (Lepetit) were added to infected FL cell cultures and embryonated eggs at concentrations from 0·001 to 100 μg/ml. All the derivatives inhibited the development of trachoma agent in cell cultures *in vitro* (Table 1).

The drugs could, however, be divided into two groups: (*a*) rifampicin and compound 33 which completely inhibited the replication of the T'ang strain of trachoma agent *in*

Table 1. INHIBITION OF T'ANG TRACHOMA AGENT BY RIFAMYCIN SV DERIVATIVES

Psittacosis	6BC	40	50	100	0	67	100	Not done			Not done			Not done		

vitro at a concentration of 0·01 μg/ml., and (*b*) compounds 18, 11 and 26 which inhibited trachoma agent at a concentration 10 and 100-fold higher than that of rifampicin. When the effect was studied in embryonated eggs *in vivo*, it was found (Table 2) that 1 μg/egg of rifampicin (compound 31) or compound 33 inhibited the replication of the Bour strain of trachoma agent. Compound 33 was slightly less effective than rifampicin in inhibiting the T'ang strain. By contrast, 100 μg/egg of compounds 18, 11 and 26 only partially inhibited the replication of the two trachoma strains in embryonated eggs. The findings *in vitro* and *in vivo* demonstrate that rifamycin SV derivatives which lack the hydrazone side chain in position 3 have a low anti-trachoma activity. The reason for the lower sensitivity of psittacosis agent to rifampicin (Table 2) is being studied.

Inhibition of replication of trachoma agent by rifamycin derivatives arises from their ability to prevent the synthesis of trachoma RNA in the developing inclusion bodies (unpublished results of B. Gutter and Y. B.). The inhibitory effect of rifampicin on trachoma RNA synthesis, like the effect on bacterial RNA polymerase[5], is to be attributed to inhibition of the agent's DNA-dependent RNA polymerase (unpublished results of I. Sarov and Y. B.). Recent studies[6] demonstrated that the macrocyclic ring of rifamycin SV is responsible for the binding of the drug to bacterial RNA polymerase; other parts of the molecule affect the permeation into intact microbial cells. Compound 31 (rifampicin) and compound 33 (Table 3), both having a hydrazone side chain in carbon 3 of the rifamycin SV chromophoric ring, are the most effective anti-trachoma compounds among the derivatives that we have studied (Table 3). The three other compounds, 18, 11 and 26, were less effective *in vitro* and very high concentrations were needed to inhibit trachoma agent *in vivo*. Compound 18, which has a short hydrazone side chain, resembled rifamycin SV in its low anti-trachoma activity (Table 3). We conclude that at least two parts of the rifampicin molecule are needed for inhibition of trachoma agent: the macrocyclic ring of the rifamycin SV molecule and the hydrazone side chain.

Table 3. RELATIONSHIP BETWEEN MOLECULAR STRUCTURE OF SIDE CHAIN IN RIFAMYCIN SV DERIVATIVES AND THEIR ANTI-TRACHOMA ACTIVITY *in vitro* AND *in vivo*

Compound[4]	Structure of side chain in position 3	Minimal inhibitory dose *In vitro* (μg/ml.)	Minimal inhibitory dose *In vivo* (μg/egg)
31 (Rifampicin)	$-CH=N-N(CH_2)_2N(CH_3)CH_2CH_2$	0·01	1·0
33	$-CH=N-N(CH_3)CH_2CH_2N(CH_3)_2$	0·01	1·0
Rifamycin SV	$-H$	0·10	> 100·0
18	$-CH=N-N(CH_3)_2$	0·10	> 100·0
11	$-CH=N-C_3H_2NS$	1·00	> 100·0
26	$-CH=N-N=CH-C_6H_5$	1·00	> 100·0

We found recently that compound 18, which lacked anti-trachoma activity, was as effective as rifampicin in inhibiting the replication of poxvirus, so demonstrating that although the hydrazone side chain of rifampicin is responsible for the anti-trachoma and anti-poxvirus activity of the drug, different parts of the hydrazone side chain were responsible for the inhibitory activities: the first part of the side chain can inhibit poxvirus replication while the terminal part is essential for the enhancement of the anti-trachoma activity of the drug. The efficiency of these derivatives of rifamycin SV in the cure of human trachoma still has to be studied.

We thank Dr L. Zeller, Professors P. Sensi and L. Silvestri from Lepetit, Milan, Italy, for the rifamycin SV derivatives. This work was aided by a grant from the World Health Organization, Geneva, and by a contribution to our Department of Virology by Ted and Frances Chanock, Los Angeles.

Effect of a DNA Tumour Virus on Antibody Forming Cells in Neonatally Infected Hamsters

LEUKAEMOGENIC viruses, such as Friend, Rauscher or Moloney virus, may markedly suppress the immune responses of infected mice, both at the cellular and humoral levels[1-10]. AKR mice developing spontaneous leukaemia also have a marked suppression of serum antibody formation preceding clinical symptoms[11]. Several current theories of carcinogenesis suggest that such deficiencies of specific immunological competence may be a necessary but not exclusive prerequisite for tumour development[12-16]. In this regard, the induction of tumours by viruses other than those associated with murine leukaemia may also depend on an inadequate immune system and/or induction of specific immunological tolerance. Because most tumour viruses induce neoantigens in infected cells, it seems probable that an immunocompetent individual would respond to the virus induced antigens[15]. Loss of immunological competence could be related to development of the tumours. This study was undertaken to determine if a non-leukaemia DNA tumour virus could affect the immunological responsiveness of experimental animals. For this purpose, SV40 tumour virus was inoculated into newborn hamsters and their subsequent immune response to sheep erythrocytes was determined at the serum and cell level, using the haemolytic plaque assay in agar gel and serological procedures. The responses of non-infected hamsters were determined simultaneously.

Newborn hamsters were injected intraperitoneally with SV40 virus prepared in monkey kidney cell cultures[17], using at least six litters for each experiment. An equal number of animals were untreated controls. Tumour development was determined by close periodic physical examination during the subsequent six months[17]. More than 95 per cent of the animals injected with virus at birth developed multiple tumours at ages of 90 to 150 days. None of the control animals developed tumours.

To determine the immunological competence of these animals, groups of four or five infected or control hamsters were challenged by intraperitoneal inoculation of 0·1 ml. of a 10 per cent suspension of washed sheep red blood cells. Antibody plaque forming cells (PFC) were determined in spleens of individual hamsters 4 days later, using the plaque assay[18]. Haemolysins and haemagglutinins were determined in serum specimens by microtitre serological tests.

Table 1. EFFECT OF AGE ON APPEARANCE OF HAEMOLYSIN FORMING CELLS IN SPLEENS OF HAMSTERS IMMUNIZED WITH SHEEP ERYTHROCYTES

Age at time of challenge immunization (days)	Average number of PFCs per spleen on day: 2	4	7	10	15	20
1– 2	< 5	< 5	< 5	39	—	135
6– 8	665	4,830	246	193	185	169
11–14	2,431	16,653	5,950	2,050	1,670	1,130
18–21	28,341	80,369	42,395	4,350	3,160	—
26–28	45,421	139,531	32,340	9,321	2,159	1,330
> 35	39,753	151,350	38,461	11,215	2,350	1,653

Groups of hamsters were injected intraperitoneally, at age indicated, with 0·1 ml. 10 per cent sheep erythrocytes; five or more animals were killed on day indicated and the average number of PFCs per spleen was determined for each group.

Normal, non-infected hamsters injected with erythrocytes at 4 to 6 weeks of age exhibited a vigorous immune response when tested 4 days after immunization (Table 1). There was a direct relationship between the age of the animal at the time of challenge and the number of PFCs. For example, normal hamsters immunized when 1 week old rarely had more than 5,000 PFCs per spleen 4 days later (at 11 days of age). Immunization of 2 week old hamsters resulted in a peak of nearly 20,000 PFCs per spleen. Hamsters which were 3 or 4 weeks old had three to five times as many PFCs, the number approaching that for the mature animals.

Hamsters injected at birth with the tumour virus also responded with significant numbers of PFCs to the red blood cells. There was little or no detectable difference between the number of PFCs in spleens of infected animals at 3 to 6 weeks of age and the corresponding controls (Table 2). Infected animals tested at 1 or 2 weeks of age had about 50 per cent fewer PFCs than control animals of the same age. The response of non-infected animals at this time was, however, generally less than 10 to 15 per cent of that which occurred in the adult control groups.

The serum antibody response to sheep erythrocytes was generally low in 1 or 2 week old hamsters, regardless of treatment. Titres were moderately higher in 3 and 4 week old hamsters, reaching a level of 1 : 200 to 1 : 600 in the 4 to 6 week old groups. There was essentially no difference in the mean titre, or range of titre, between infected and control hamsters at any age.

These results revealed little, if any, effect on the immune responsiveness of young adult hamsters to sheep erythrocytes during the latent period of SV40 virus induced oncogenesis. There was, however, a suggestion of a slight to moderate depression of development of immune competence to this antigen during the early period of immunological maturation (1 to 2 weeks of age). The significance of such a moderate and temporary deficiency at the cellular level in such young animals is not clear, but it is obvious that at 3 or 4 weeks of age, or later, SV40 infected animals responded as well as non-infected controls. Further, the serological titres, which were generally quite low in the younger animals, were similar for all infected and control groups. Thus immune suppression—at least to sheep erythrocytes—was not a significant factor in tumour induction by a DNA tumour virus, such as SV40, as it is in mice infected with an RNA leukaemogenic virus.

Table 2. EFFECT OF SV40 INFECTION AT BIRTH ON THE IMMUNE RESPONSE OF HAMSTERS TO SHEEP ERYTHROCYTES AT VARIOUS AGES

Age at time of challenge immunization (days)	Mean peak immune response to sheep erythrocytes: Control mice PFC/spleen	Control mice PFC/10^6 spleen cells	Control mice Serum titre	SV40 infected mice PFC/spleen	SV40 infected mice PFC/10^6 spleen cells	SV40 infected mice Serum titre
1	< 100	< 1	< 1 : 4	< 100	< 1	< 1 : 4
7	1,738	163	1 : 8	889	59	1 : 4
14	19.965	229	1 : 27	17,861	183	1 : 17
21	62,695	289	1 : 78	49,215	275	1 : 67
28	139,581	314	1 : 219	132,850	319	1 : 211
42	153,580	386	1 : 135	156,385	335	1 : 202

Groups of hamsters were untreated or injected intraperitoneally with SV40 virus on the day of birth; five or more animals were immunized intraperitoneally with 0·1 ml. 10 per cent sheep erythrocytes at age indicated and killed 4 days later.

Effects of Adenoviruses on the Chromosomes of Normal Human Cells and Cells Trisomic for an *E* Chromosome

NON-RANDOM damage to the chromosomes of human embryo kidney (HEK) cells by adenovirus type 12 (*in vitro*) has been reported by Zur Hausen[1]. We have obtained similar results with adenovirus type 12 in fibroblasts grown from human embryo lung (HEL) and from skin biopsy samples, as well as in the epithelial HEK cells.

HEK and HEL cells were obtained from embryos removed by therapeutic abortion. Fibroblast cultures were also obtained from outgrowths of skin biopsy samples taken from normal and genetically abnormal children and adults. The cells were grown in 5 cm plastic Petri dishes. The medium used for cell cultivation was Ham's F10 (ref. 2) + 10 per cent tryptose phosphate broth and 20 per cent foetal calf serum. All cultures were incubated at 37° C in an atmosphere of 5 per cent CO_2 in air. Adenovirus strains were supplied by Dr H. G. Pereira (National Institute for Medical Research, Mill Hill, London), grown in HEK cells and purified by the method of Russell, Valentine and Pereira[3].

For cytogenetic studies, cells washed with phosphate buffered saline were infected by adsorbing the virus inoculum (input multiplicity = 1) for 3 h at 37° C. After the adsorption period the cells were washed with phosphate buffered saline and reincubated with growth medium. Colcemid was added to the cultures 24 h after virus adsorption. Three hours later, the cells were removed from the dishes with 0·25 per cent trypsin, centrifuged at 800 r.p.m. and resuspended in 0·075 M KCl. After incubation at 37° C for 5 min, the cells were again centrifuged and then fixed in a mixture of three parts absolute methyl alcohol and one part glacial acetic acid. Slide preparations were made by drying drops of fixed cell suspension on slides at room temperature, followed by staining with acetic orcein; they were then mounted in euparal.

In Fig. 1, the No. 1 and No. 17 chromosomes show the typical damage found after *in vitro* infection with adenovirus type 12. Experiments with other adenovirus serotypes (types 2, 5, 7 and 18) have resulted in random damage to the chromosomes, and, where a No. 17 was involved, the damage has occurred at positions on the chromatids different from that usually affected by adenovirus type 12. In Fig. 2, the distribution of chromosomal damage induced by type 12 is compared with that found after *in vitro* infection with type 18. The results with type 18 are more compatible with a random distribution of damage: a histogram based on the relative lengths[4] of the individual chromosomes has a similar appearance (Fig. 3). There may be some degree of specificity in the response of the No. 17 chromosomes to adenovirus type 18 infection.

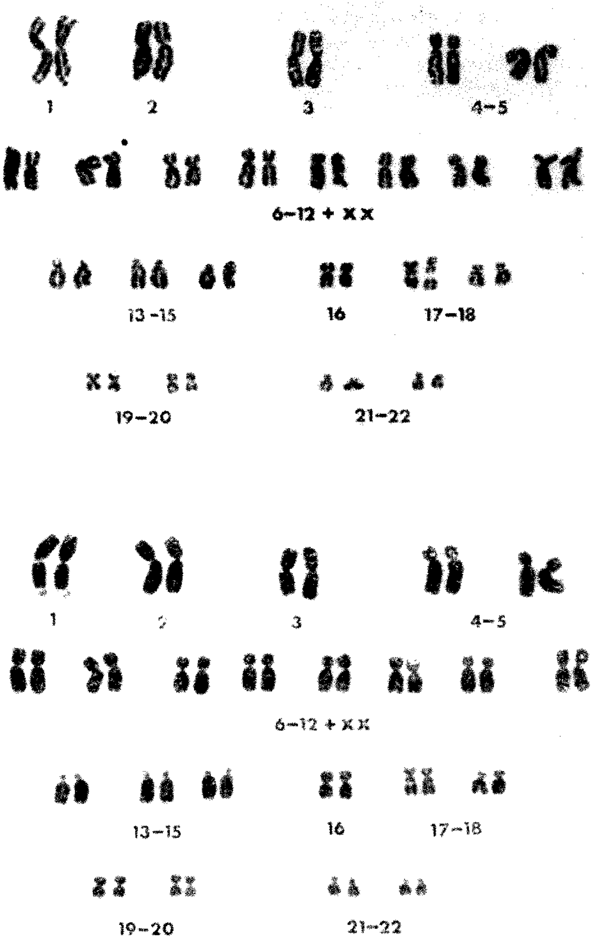

Fig. 1. Karyotypes of two cells showing non-random damage to chromosomes No. 1 and No. 17 induced by adenovirus type 12 *in vitro*.

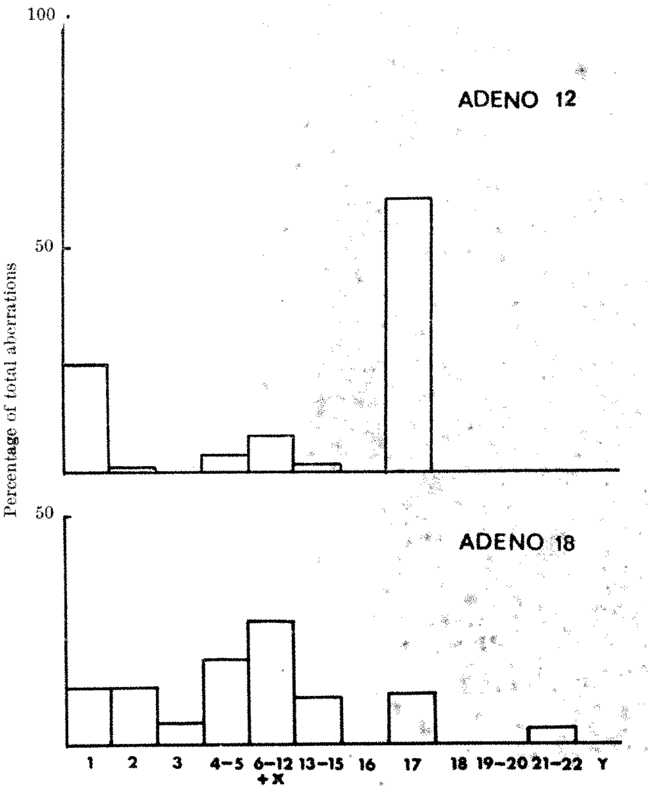

Fig. 2. Distribution of damage to chromosomes induced by adenovirus types 12 and 18.

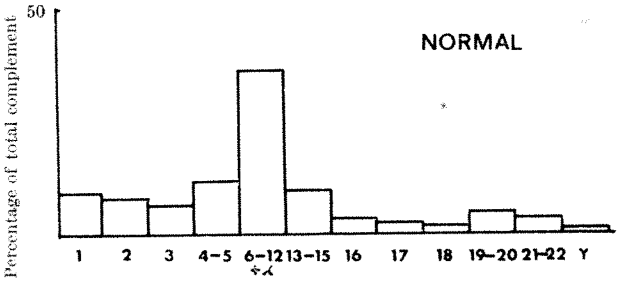

Fig. 3. Distribution of chromosomal material based on chromosome lengths (Denver classification).

Trisomy *E* (Edwards' syndrome), in which severe malformations—usually fatal in the first year of life—occur, was originally described as being associated with an extra chromosome, No. 17 (ref. 5). Patau *et al.*[6] stated that the extra chromosome was a No. 18 and autoradiographic studies carried out by Yunis *et al.*[7] supported this contention.

Using the effect of adenovirus type 12 on chromosome No. 17 as a marker, the response of the five *E* group autosomes to infection by this virus was examined. Experiments were carried out as described for normal cells, 100 metaphases being examined for each specimen. Damage to the No. 17 chromosomes was similar to that found in normal human cells, but in no cell has the morphology of more than two *E* group autosomes been affected by the virus.

Table 1. NON-RANDOM DAMAGE BY ADENOVIRUS TYPE 12 TO *E* GROUP CHROMOSOMES FROM NORMAL AND GENETICALLY ABNORMAL (TRISOMY *E*) CELLS

	No damage to *E* group	Damage to one *E*	Damage to two *E*	Damage to three *E*	Total cells
Normal	76	78	46	0	200
Trisomy *E*	158	26	16	0	200

In Table 1 the numbers of cells with damage to *E* group chromosomes are shown, based on 100 cells from each of two normal subjects and 100 cells from each of two subjects with trisomy *E*. The decreased number of cells

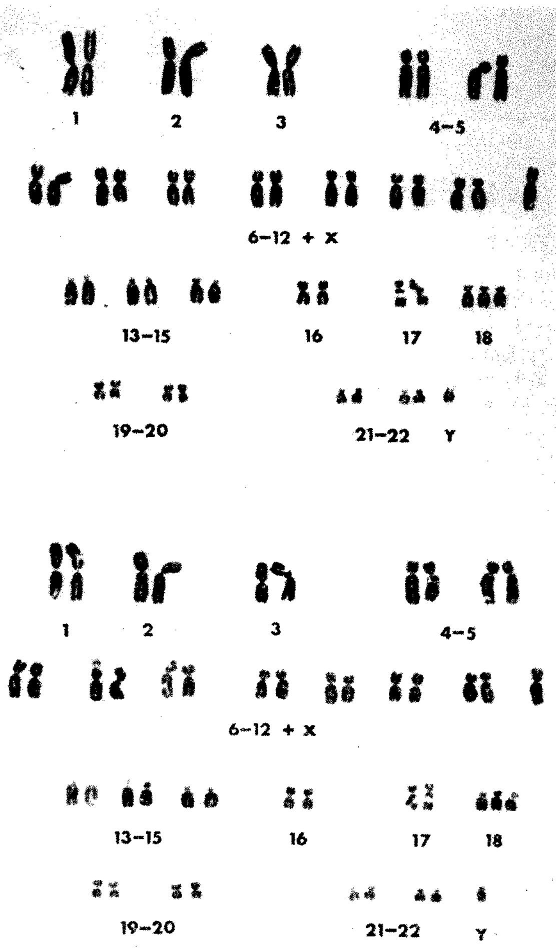

Fig. 4. Karyotypes of two cells, from an infant with Edwards' syndrome, infected *in vitro* with adenovirus type 12.

with damage to *E* group chromosomes in the trisomy *E* samples reflects the difference in virus susceptibility of these cells in comparison with the normal cells.

Fig. 4 shows the chromosomes of two virus-infected cells from a male infant with Edwards' syndrome, in which the typical non-random damage induced by adenovirus type 12 to the No. 17 chromosomes can be seen.

These results offer further evidence to support identification of the extra chromosome in Edwards' syndrome as a No. 18.

I thank Dr H. G. Pereira for virus samples, Dr Angela Taylor for a skin specimen from a case of Edwards' syndrome, Professor D. G. Harnden and Dr Patricia Jacobs for encouragement and advice and Mrs Katie Vause for technical assistance.

Transformation and Virus Growth by Murine Sarcoma Viruses in Human Cells

In the study of neoplastic transformation of human cells in culture, the quantitative systems so far described have used only the DNA-containing tumour viruses SV40 (ref. 1) and adenovirus type 12 (ref. 2). Various factors, both genetic[3] and environmental[4], influence the efficiency of transformation with these viruses. We describe here a quantitative transformation system using an RNA-containing tumour virus, murine sarcoma virus (MSV)[5]. The transformation of human cells by MSV is inefficient, but in optimal conditions (logarithmically growing cells and certain highly susceptible cell strains) both cell transformation and virus growth can be demonstrated.

Human fibroblast strains derived from a variety of sources, including embryonic lung and kidney, newborn foreskin, and adult skin, were grown in Dulbecco's medium supplemented with 10 per cent calf serum. MSV stocks were obtained from two sources: (1) a cloned line of Molony sarcoma virus (MSV–M)-transformed Balb/3T3 mouse cells[6]; (2) a Kirsten sarcoma virus (MSV–Ki)-transformed rat cell line[7] supplied by Dr V. Klement (Children's Hospital, Los Angeles). Both *in vitro* transformed lines produce high titres of MSV. The virus pools, obtained from supernatants two days after medium change, were first clarified by low speed centrifugation and then passed through 0·45 µm 'Millipore' filters. Human strains were infected within 24 hours after inoculation of 2–3 × 10^5 cells into 15 cm^2 Falcon flasks. After a one hour adsorption period medium was added and then changed twice weekly.

As early as 5–6 days after infection, focal areas of more refractile cells were seen. These areas increased in size during the next week. Fig. 1*a* shows an example of a focus 12 days after virus exposure. Most of the cells were fusiform in shape, and many contained large cytoplasmic vacuoles. The number of foci did not increase after two weeks, but after that time in certain strains a pronounced proliferative effect with multilayered cell growth was noted (Fig. 1*b*). The number of transformed foci was counted at 14 days; the same virus preparations produced foci somewhat more rapidly on mouse and rat cells, and here foci were scored at 7 days. Balb/3T3 was used to titre MSV–M and the rat NRK line was used to assay MSV–Ki. While each virus will grow on a variety of rodent cell cultures, the above cells were found to be the most susceptible.

Table 1. FOCUS-FORMING ABILITY OF MURINE SARCOMA VIRUSES ON RODENT AND HUMAN CELLS

	Rodent cells (FFU/ml.)*	Human cells (FFU/ml.)†	Relative focus forming ability ‡
MSV–Ki	3·4 × 10^5	1·1 × 10^3	3 × 10^2
MSV–M	5·0 × 10^4	5	1 × 10^4

* Assayed at 7 days after infection: MSV-Ki titred on NRK and MSV-M titred on Balb/3T3.

† Assayed at 14 days on newborn foreskin strain 8727 and adult skin fibroblast strains R.M. and B.F.

‡ Titre (foci × dilution) on mouse cells/titre (foci × dilution) on human cells.

Human cell cultures were stained for murine sarcoma–leukaemia antigen by an indirect fluorescent antibody method using rat anti-MSV serum and fluorescein-conjugated goat anti-rat serum (unpublished data of W. P. Rowe, J. W. Hartley and R. E. Wilsnak). Seven days after infection focal areas showing characteristic cytoplasmic staining were seen; they contained 5–10 cells per focus. Uninfected human cultures showed no staining, nor did MSV-infected cultures that were stained with control rat serum.

Eighteen human fibroblast strains, each derived from a different person, were tested. Eleven have shown clear evidence of focus formation by MSV. The number of foci

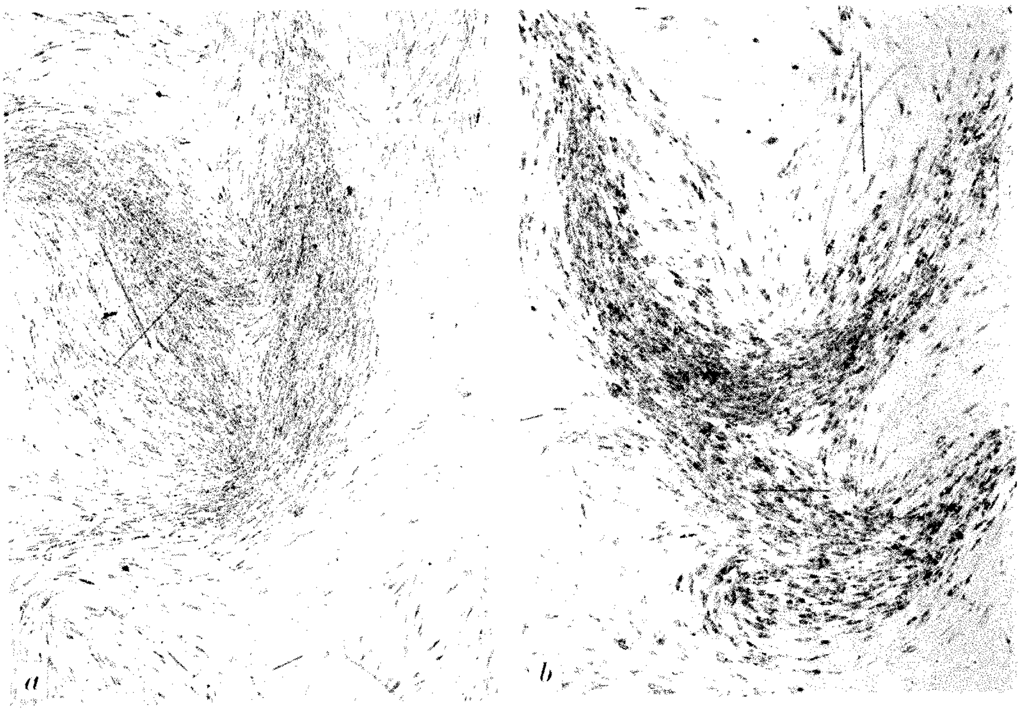

Fig. 1. *a*, A transformed focus appearing on human strain B.F. at 12 days after infection; *b*, a more advanced focus seen at 16 days on strain R.M. (× 20.)

ranged from one or two per plate up to several hundred with the most susceptible strains. For MSV–Ki, roughly 3×10^2 focus forming units (FFU) were needed to produce one focus on a susceptible human cell; with the virus from MSV–Balb/3T3 approximately 30 times as many FFU were required (Table 1). Dilution of each virus stock resulted in a decrease in the number of foci most consistent with a "one hit" pattern. That the foci were due to MSV and not to the associated helper leukaemia virus was shown by using sarcoma virus-free leukaemia stocks at comparable or higher titres and finding no foci on any of the human cells tested.

The cultures at two weeks after infection showed evidence of virus replication by several methods. Electron microscopic sections of foci showed typical budding C-type particles[8]. Sucrose gradient banding of the supernatant fluid showed a peak of radioactivity at a buoyant density of 1·16 g/cm^3, the density characteristic of MSV[9]. Focal areas of transformed cells were isolated by cloning. After six transfers and after over three months, morphologically transformed cells could still be seen. These cultures still contained fluorescent antibody staining cells and continued to produce C-type particles. Using filtered supernatant preparations from MSV-infected human cells, biological activity was demonstrated by focus formation both on mouse and human cells. The virus obtained still produced foci considerably more efficiently on mouse cells than on human cells, suggesting little, if any, host cell modification. DEAE–dextran, which increases the efficiency of transformation with several RNA-containing tumour viruses, also increased the efficiency in this system, but did not alter the relative focus forming ability.

This communication shows that murine tumour viruses can reproducibly infect and morphologically transform many strains of human cells. Certain avian sarcoma viruses have also been shown to infect and morphologically alter human cells[10]. With the murine viruses Bernard *et al.*[11] have reported morphological alteration and virus growth using one human embryonic strain, WI38. The ability of the sarcoma viruses of avian and murine origin both to grow in and also to transform human cells of diverse origin increases the possibility that these or similar agents may, on occasion, cross species barriers to cause tumours in man.

Effect of ALS Globulins on Amino-acid Incorporation by Human Peripheral Lymphocytes

THE mechanism by which antilymphocyte globulins act on immunocompetent cells remains unknown. Recent studies have demonstrated that antilymphocyte sera (ALS) and phytohaemagglutinin (PHA) display a similarity in their action on the lymphocyte[1–6]. We have studied the action of these substances on the incorporation of amino-acids by human peripheral lymphocytes.

Human blood (400 ml.) drawn by venous puncture was collected on heparin (2·5 mg for 15 ml. of blood). Lymphocytes were isolated by filtration on synthetic fibre according to a technique described previously[7]. After filtration

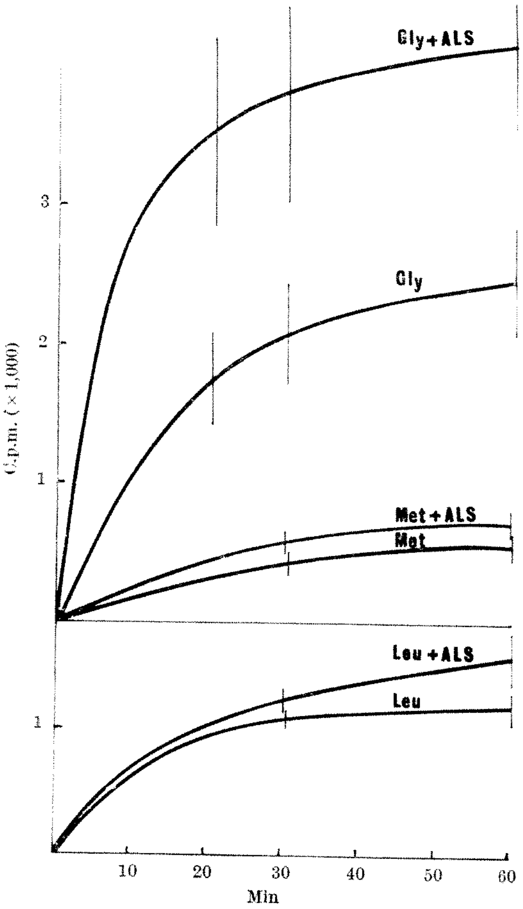

Fig. 1. Action of horse ALS on the rate of incorporation *in vitro* of glycine (Gly), methionine (Met) and leucine (Leu). 15×10^6 lymphocytes were incubated in 1·5 ml. of Krebs–Ringer phosphate buffer (*p*H 7·4), containing ^{3}H or ^{14}C-labelled amino-acid (3·33 mmole; 0·33 μCi/mmole) with or without ALS (0·1 ml. of a solution rich in IgG, 15 mg/ml.). The titre of the preparation was 1/1,024. The rate of incorporation (c.p.m.) is expressed as a function of time. The confidence limit (95 per cent) is indicated by a vertical line.

the blood was precipitated by dextran (molecular weight 500,000), and the supernatant was centrifuged in the cold at 250*g* for 20 min. The red cells in the pellet were haemolysed by adding a solution of NH_4Cl (0·87 per cent). The mixture was centrifuged in the cold at 250*g* for 20 min and the final pellet washed in saline and resuspended in saline.

Lymphocytes were obtained in a purity of 95 per cent, the remainder being polymorphonuclear leucocytes. The yield of lymphocytes was about 20 ml. of a suspension containing 20×10^6–25×10^6 cells/ml. They were incubated in the presence of amino-acids labelled with ^{14}C or ^{3}H for relatively short periods (60 min). When phytohaemagglutinin was used (PHA-M, Difco, in vials of 5 ml.), it was added to the incubation medium at the same time as the labelled amino-acid. The same procedure applies to the use of fractions of ALS.

Horse antilymphocytic sera were prepared by Dr Carraz of the Pasteur Institute of Lyon, by immunization with human thoracic duct lymphocytes[8]. The antiserum obtained was decomplemented, then absorbed on human red cells. A fraction enriched in antilymphocyte globulins was prepared by precipitation of the serum at 4° C with ammonium sulphate (40 per cent saturation), which is finally eliminated by dialysis. The precipitate obtained was taken up in saline to the same volume as the initial serum. Rabbit antilymphocytic sera were obtained by immunizing rabbits with human peripheral lymphocytes. The precipitate obtained with ammonium sulphate (40 per cent saturation) was dissolved and fractionated in the cold by electrophoresis on Pevikon media with 0·18 M borate buffer (*p*H 8·2), according to a previously reported technique[9]. In this way the γG-globulin (IgG) and albumin fractions are isolated. The same technique was used to prepare IgG and albumin fractions from normal decomplemented and absorbed horse and rabbit sera.

The potency of the ALS was measured by its cytotoxic action on normal human lymphocytes: the lymphocytotoxic test of Engelfriet[10] with trypan blue was used. The titres given are the highest dilutions which give more than 15 per cent dead cells. The titres for the different horse antilymphocyte globulins were 1/1,024; for rabbit IgG fractions the range was 1/256–1/512.

The influence of horse ALS on the rate of incorporation of methionine, leucine and glycine by human lymphocytes *in vitro* is illustrated in Fig. 1. A significant increase in the rate of incorporation is obtained immediately in the case of glycine; in the presence of an identical amount of antilymphocyte globulin it takes about 30 min of incubation for leucine and 60 min for methionine to have a significant effect. Subsequent studies (unpublished) have demonstrated that the incorporation of leucine and glycine by human lymphocytes, like that by other cells, requires different carriers at the level of the cellular membrane. We postulate that the stimulation by ALS is related to its direct action on certain of these transport systems. (The interpretation of the increased rate of incorporation in the case of leucine must take into account the fact that certain lots of ALS have sufficient cytotoxic power to damage the cellular membrane in about 30 min.)

The action of ALS is also dependent on its origin (Fig. 2). Equal amounts of various IgG fractions from horse ALS, all having the same cytotoxic titre, increase the rate of incorporation of glycine to different extents. On the other hand, IgG fractions purified from the different rabbit ALS preparations studied so far had an inhibitory action. This constitutes additional proof for the heterogeneity of antilymphocyte globulins. In every case, however, their action is immediate and manifest in the first 30 min. Within the limits of the concentrations used, the rate of incorporation of glycine increases with the dose of ALS (Fig. 3). The inhibitory action of the corresponding proteins of normal horse serum is also dependent on the dose.

Fig. 4 indicates that PHA exerts an inhibitory action on the rate of incorporation of glycine, this effect being directly related to concentration. There therefore seems to be a difference between the mode of action of horse

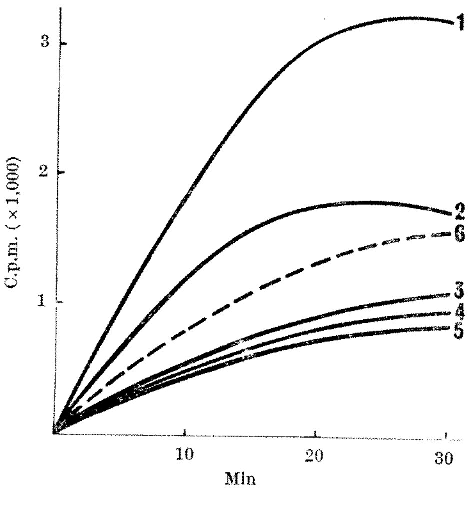

Fig. 2. Action of ALS of different origins on the rate of incorporation of glycine by peripheral human lymphocytes. 1 and 2: preparations of horse ALS rich in IgG (15 mg/ml.); the titre of both lots was 1/1,024. 3, 4 and 5: rabbit IgG fractions (13 mg/ml.) purified from the corresponding ALS. The titres of the different fractions were respectively 1/256, 1/512 and 1/256. 6: incorporation of glycine without ALS.

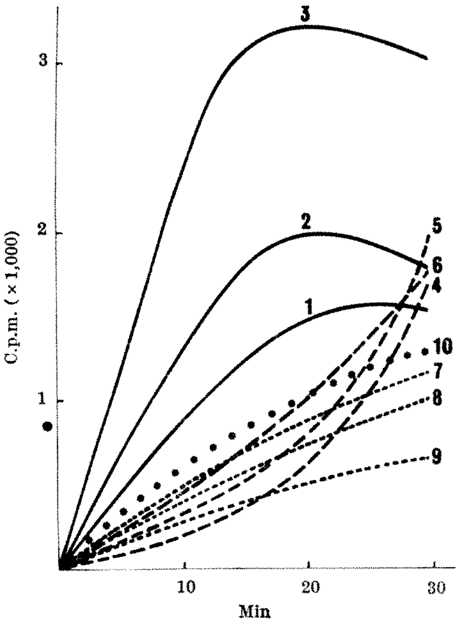

Fig. 3. Influence of the amount of ALS on the rate of incorporation of glycine by peripheral human lymphocytes. 1, 2 and 3: preparations of horse ALS rich in IgG (15 mg/ml.) at increasing doses (0·3 mg, 2·25 mg and 3·75 mg, respectively). 4, 5 and 6: IgG fractions (15 mg/ml.) purified from normal horse serum in increasing doses (0·3 mg, 2·25 mg and 3·75 mg, respectively). 7, 8 and 9: albumin fractions of normal horse serum, brought to the same volume as the initial serum (0·02 ml., 0·15 ml. and 0·25 ml., respectively). 10: incorporation of glycine without heterologous proteins.

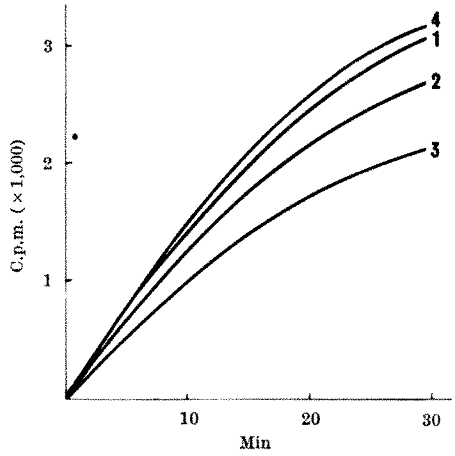

Fig. 4. Influence of different concentration of PHA on the rate of incorporation of glycine by human peripheral lymphocytes. 'Bacto-PHA-M' (Difco Laboratory) was dissolved in 5 ml. of saline. 1, 2 and 3: final dilution of the stock solution of PHA (1/100, 1/50 and 1/10, respectively). 4: incorporation of glycine in the absence of PHA.

ALS and PHA, the rate of incorporation of glycine in peripheral lymphocytes being increased by ALS but decreased by PHA. We are investigating whether this activation is the result of a direct action on the transport system for glycine by the lymphocyte membrane.

We thank Dr M. Carraz, Pasteur Institute, Lyon, for providing us with horse ALS; and M. Terrier for technical assistance.

Acute Childhood Leukaemia in Relation to the HL-A Human Transplantation Genes

The expectation that certain human diseases might show a high statistical correlation with certain transplantation genes is based on analogy with mouse systems[1]. The H-2b gene in mice is associated with a low incidence of tumours and with great longevity in three different inbred strains[2]. Another transplantation gene, the H-2k gene, confers in homozygous form an almost 100 per cent susceptibility to the Gross leukaemia virus[3] and a non-susceptibility to the Tennant leukaemia virus[4].

Attempting to find out whether in man certain HL-A genes might correlate with human leukaemia, we adopted two rules. First, we would deal with a very well defined type of leukaemia. We therefore investigated acute childhood leukaemia because of its rather consistent lymphatic origin, its clinical course and its restricted age distribution. The second rule was that we would look for an HL-A correlation on the basis of genotypic as well as phenotypic data. The H-2k gene in mice is manifested by the serological specificities 1, 3, 5, 8, 11 and 25. Many of these, in combination with further specificities, are found on other mouse transplantation genes, for example, on H-2a; nevertheless, only one particular collection of specificities denotes the H-2k gene. Failure to appreciate these rules may have prevented Kourilsky *et al.*[5] from finding any correlation between the HL-A system and "acute leukaemia" in man.

We investigated ten families in each of which one child was afflicted with acute lymphatic leukaemia and in which at least one other sibling was available for HL-A typing. Including leukaemics and their siblings, a total of twenty-three children plus all twenty parents were studied. The HL-A type of each person was determined with the microlymphocytotoxicity test[6]. We used anti-sera determining specificities HL-A 1, 2, 3, 9, "Thompson", Da-17, and Lc-26 at the first sublocus of the HL-A system. At the second sublocus, the following were determined: HL-A 5, 7, 8, Lc-15, "Gallegos", and "Merritt"[1]. A collection of known HL-A specificities which migrate as a unit in families is known as a "haplotype"; from a practical serological standpoint the terms "gene" and "haplotype" are similar. Because each HL-A haplotype is reflected by none or by one (but almost never more than one) specificity from each sublocus, a total of fifty-six possible haplotypes can be envisaged. This figure assumes a "null" haplotype at each sublocus. By immunogenetic analysis of our typing data[1], the actual haplotype of each member of our ten families was deduced, including the haplotypes of the ten leukaemic children. Separate but similar studies of twenty-five random normal families provided us with sufficient random, parental haplotypic data (100 parental HL-A chromosomes) to estimate normal frequencies in our population. Whether any particular haplotype appeared more often than expected among the leukaemics might then be determined.

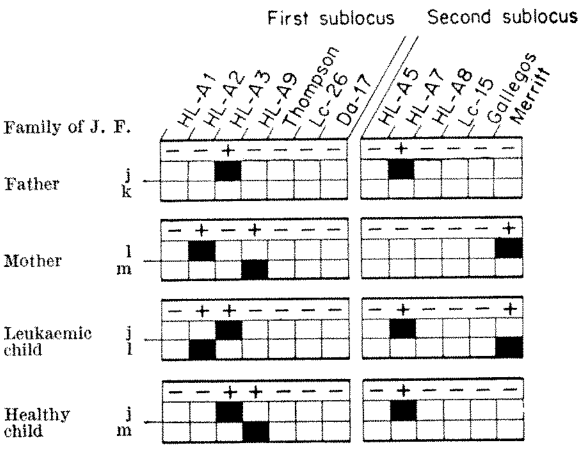

Fig. 1. Immunogenetic analysis of a leukaemic family. Phenotypic data are given as + or − under each specificity and for each family member. Genotypes can now be derived by simple inspection assuming the two subloci and the rule of complete mutual exclusivity at each of them.

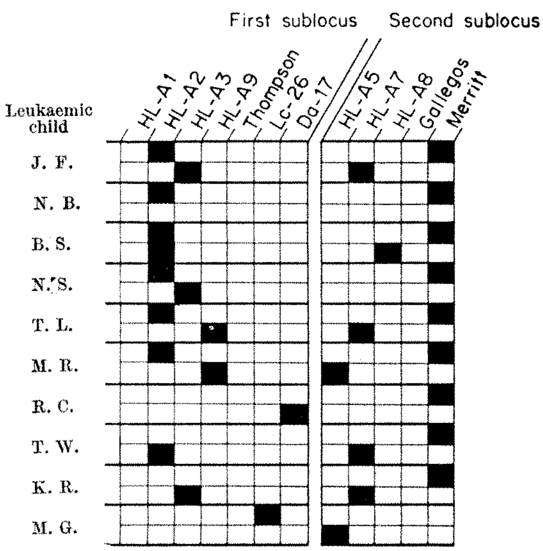

Fig. 2. HL-A genotypes of ten unrelated children with acute lymphatic leukaemia.

Results obtained with one of the ten families are shown in Fig. 1. The HL-A haplotype of the leukaemic child was HL-A 3, 7/2, Merritt. We shall concentrate on this second, HL-A 2, Merritt haplotype, designated the l-haplotype in Fig. 1. In our normal population the frequency of the l-haplotype was only five per cent, but six of our ten leukaemic children had this haplotype on one of their two HL-A chromosomes. The probability of this or a greater frequency happening by chance is less than 0·0025.

Fig. 2 gives the haplotypes of all ten unrelated leukaemic children. The frequency of the l-haplotype is evident. We note also that none of the twenty haplotypes carried the HL-A 1 specificity. The frequency of HL-A 1 in any combination was 0·25 in our normal population. The probability therefore of all ten leukaemics being HL-A 1-negative is about 0·016. We note furthermore (Fig. 2) that nine children were phenotypically Merritt positive. The frequency of the Merritt specificity in any combination was 0·20, for it also occurred in association with specificities other than HL-A 2. In these circumstances the probability of nine of ten persons with one or more haplotypes carrying the Merritt specificity is less than 0·035.

There can be little doubt as to the statistical significance of at least the first of these probabilities in view of its magnitude. Assuming for the sake of discussion that acute childhood leukaemia has a viral origin, the possession of the HL-A 2, Merritt haplotype may indicate an increased susceptibility to a particular leukaemia virus present near Los Angeles. Different associations might be found in other localities. Healthy persons also possess the HL-A 2, Merritt haplotype, including parents and siblings of the leukaemic children studied here. We are thus dealing not with an absolute but with an enhanced susceptibility, and additional factors must come into play in the pathogenesis of the leukaemia. Whether the presence of the Merritt specificity irrespective of HL-A 2 is meaningful in showing enhanced susceptibility to leukaemia, and whether the presence of the HL-A 1 specificity indicates resistance to the form of leukaemia studied here, must await the accumulation of a larger series. The ability to predict that persons with such and such an HL-A genotype are "at risk" with respect to acute leukaemia, persons with another genotype "at risk" for some other disease, would be of obvious value. The present study suggests that exploration of the HL-A system in the manner outlined might yield these kinds of data.

Enzyme Patterns in Tetraparental Mouse Liver

Tetraparental mice are produced by fusing two eight-cell stage embryos. If the two embryos originate from different inbred strains, allelic differences between the strains produce mosaic patterns in the adult tetraparental which make possible inferences about development[1-3]. Mintz and Baker have elegantly used this concept to confirm that somatic muscle cells fuse during development[4]. They used an isozyme variant of isocitrate dehydrogenase, and found hybrid enzyme patterns in somatic muscle tissue. Only parental patterns were demonstrable in other tissues, such as the liver.

Mouse liver contains other enzymes which have known genetic variants. An interesting example is β-glucuronidase, which has high activity in some strains, low activity in others and intermediate activity in high–low hybrids. The high and low traits segregate as simple mendelian alleles (ref. 5, and personal communication from L. A. Herzenberg). The intermediate activity of β-glucuronidase in hybrid livers makes the enzyme a potentially useful marker to determine the mix of a tetraparental liver. This use was contemplated for an experiment different from that described here, but when the assay was carried out, some surprising variation in the data led to the experiment described here. The results suggest that the liver may be clonal in structure.

The livers of six C57Bl/10SnJ–C3H/HeJ tetraparental mice were removed after death, washed immediately in phosphate-buffered saline to remove excess blood and frozen between two blocks of dry ice. They were kept at or below −78·5° C until use. Samples weighing roughly 45 mg were chipped from the frozen organ, weighed, diluted 1 : 100 with distilled water, and homogenized in the cold with a Potter–Elvehjem glass homogenizer. Because the β-glucuronidase mutation affects intracellular location as well as certain physical properties of the enzyme[6], this stage was carried out in a rigidly standardized manner, in conditions known not to disrupt mitochondria (a setting of 4·5 on a Tri-R Stir-R homogenizer, using six passes of the pestle (personal communication from T. P. Bennett). The β-glucuronidase activity was measured by the method of Talalay *et al.*[7], as modified by Paigen[6], and all assays were carried out on the uncentrifuged crude homogenate. Each assay was performed in duplicate. The enzyme exhibits first order kinetics in the conditions used. Artificial mixtures of C57Bl/10SnJ and C3H/HeJ liver homogenates had activities that were proportionally intermediate. Assaying the six tetraparental livers on the first trial gave values ranging between the two parental values. The same picture emerged on the second trial, but the glucuronidase value for a given piece was in some cases quite different from that for the previous piece from the same tetraparental liver. The parental and hybrid values were much more consistent. To study this variation systematically, three of the tetraparental livers that had varied the most (T_3, T_4 and T_7) and one that had not varied more than the non-chimaeric pieces (T_{11}) were selected and analysed in seven experiments. In each experiment six approximately equal pieces of a tetraparental liver were analysed at the same time as six identically treated pieces of hybrid liver; once, twice or three times on a given liver. The mean, range and standard error of the mean for each set of six tetraparental pieces and paired hybrid pieces are given in Table 1. The standard errors of the two types of liver are significantly different, even when T_{11} is included (*T* test, $P < 0{\cdot}001$).

Table 1. β-GLUCURONIDASE ACTIVITY, IN μg PHENOLPHTHALEIN/G LIVER RELEASED FROM PHENOLPHTHALEIN GLUCURONIDE IN ONE HOUR AT 38° C

	Tetraparental livers				F₁ livers			
Exp. No.	Liver No.	Mean, 6 samples	Range	Standard error	Liver No.	Mean, 6 samples	Range	Standard error
1	T_3	1,370	1,100–1,900	132	F_7	2,090	2,015–2,150	27·4
2	T_4	2,200	1,015–3,210	302	F_6	1,805	1,575–1,965	66·7
3	T_4	2,120	1,645–2,615	160	F_7	1,955	1,855–2,050	26·2
4	T_4	2,205	1,930–2,565	117	F_4	1,910	1,785–1,995	33·8
5	T_7	2,610	1,595–3,065	219	F_5	2,200	2,065–2,360	47·9
6	T_7	1,440	1,060–2,150	152	F_4	1,980	1,900–2,040	27·8
7	T_{11}	3,605	3,390–3,960	85	F_7	2,050	1,925–2,235	37·3

The means and standard errors of six livers each from C57Bl/10SnJ, C3H/HeJ, and C57Bl/10SnJ–C3H/HeJ hybrids are 3,620 ± 223, 417 ± 9·3, and 2,050 ± 82·3 γ/g respectively.

The most obvious interpretation of the differential variation is that the cells producing the different values for β-glucuronidase are clonally distributed in the tetraparental liver. This conclusion is strengthened by rough internal consistency within the data. Tetraparental livers with an overall β-glucuronidase value close to that of the hybrid control in general have a higher variance than those whose activities approach parental values, as would be expected on a binomial sampling model. For example, liver T_{11}, the overall estimate of which is about the same as the C57Bl/10SnJ parent, has a sample variance which is just slightly above the highest hybrid variance. The high value for β-glucuronidase in this liver, coupled with its expected low variance, serves as an internal control, making it unlikely that differential treatment of tetraparental and hybrid livers produced the differential variance.

The binomial nature of the experimental situation allows an estimate of the number of clones found in the liver. Intuitively, if the clone size is very small relative to sample size (which was approximately 1/20 of the liver) there will be very little variance and, as this ratio increases, so will the variance, until one is dealing with a bimodal distribution. The theoretical variance of a given clone size and constant sample size may be obtained from the binomial distribution, if the assumption is made that all clones are equal in size and the average clone size is smaller than the average sample size. The variance V, expressed on a zero to one scale, then equals pq/N, and $N = pq/V$. In this equation p and q are the overall estimates of parental mix in the liver, expressed as fractions of the parental strains (again on a zero to one scale) and N is the number of clones in a sample. The experimental variance is assumed to be that of the hybrid liver, and is subtracted. The estimate, derived from all six experiments (excluding T_{11}), is $N = 17{\cdot}2 \pm 4{\cdot}12$ standard error of the mean, range $= 8{\cdot}06$ to $32{\cdot}8$. The conclusion that the liver is indeed clonal awaits confirmation by enzyme histochemistry.

I thank my colleagues for lively discussions and the use of their facilities. I especially thank Mr Jerry Bona for mathematical consultation. This work was performed under an institutional grant from Harvard University.

Effect of Serum from Irradiated Rats on Gastrointestinal Function

A STRONG gustatory aversion results when an animal consumes a distinctively flavoured fluid during exposure to sublethal doses (10–30 r.) of ionizing radiation[1]. Similar aversive reactions are observed when wild rodents consume poisoned food baits[2]; or when laboratory rats drink flavoured water and are subsequently injected with an emetic drug[3]; or when these animals are injected with a small amount of serum (1·2 ml.) from a donor exposed to massive irradiation (30 krad) from cobalt 60 (ref. 4).

The gastrointestinal tract exhibits transient functional changes when exposed to ionizing radiation[5,6]. Thus it seems that the gustatory aversion which follows radiation exposure is a conditioned response resulting from the association of a particular flavour with "radiation sickness". A circulation by-product of energy absorption which causes gastrointestinal disturbance could account for the malaise as well as the aversive reactions observed. This hypothesis is not only of significance for the behavioural investigations, but is also of potential importance for clinical understanding and management.

To test this hypothesis we investigated the effect of both crude serum and serum fractions from irradiated donor rats on *in vitro* preparations of rat ileum and uterus. The *in vitro* preparation was in a standard 50 ml. chamber in which 2–3 cm pieces of tissue were bathed in oxygenated (5 per cent CO_2, 95 per cent O_2) Tyrode solution at 38·5° C. Recordings were made using a Harvard Apparatus Co. mechano-transducer and paper chart reader. After each test, the preparation was washed with 200 ml. of

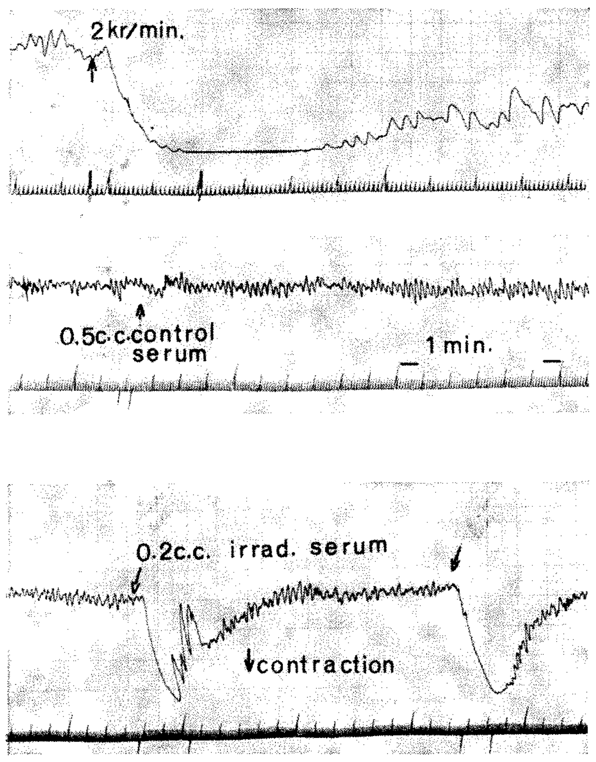

Fig. 1.

fresh Tyrode solution. Initially we found that serum from both irradiated and control rats produced an immediate increase in tone of several minutes' duration when topically administered *in vitro*. In many cases, however, the effect of the serum from irradiated donors was more pronounced than that from control donors.

Testing the assumption that both samples contained bradykinin which caused the increased tone and masked the irradiation effect, all *in vitro* solutions were perfused with sodium salicylate (10–20 mg/50 ml.), a potent blocker of bradykinin. In these conditions the addition of 0·2 ml. of the irradiated serum (10, 20 or 30 krad) to the bath caused a marked and prolonged contractile effect in thirty ileum preparations, while the control serum had little effect. Fig. 1 shows the response of an *in vitro* gut preparation to irradiated serum (bottom trace) along with a response to direct X-ray exposure (top trace). Control serum (middle trace) produced no changes. These data support the notion that radiation conditioned aversion is due to a humoral agent which produces noxious stimuli by affecting gastrointestinal smooth muscle function.

In an attempt to ascertain the nature of this putative humoral agent we used a 'Sephadex' gel fractionation procedure and tested the fractions on muscle bath preparations of rat or guinea-pig ileum. The initial fractionation, using 'Sephadex *G*–25', yielded two groups of active fractions in the irradiated serum, and one group of active fractions in the control serum. Both irradiated and control sera contained a fraction which elutes early (a protein or polypeptide). Assuming that this early fraction contained bradykinin, we pretreated ileum strips with sodium salicylate (20 mg/50 ml. Tyrode) which had effectively blocked the contraction of the gut evoked by control serum, but not that in response to serum from irradiated rats.

The other active fraction, found only in the serum from irradiated donors, elutes from the 'Sephadex' column at a position corresponding to some of the common biogenic amines. A number of pharmacological blocking agents were used to identify this second active fraction. Ten separate bioassays were performed with 1/1,000 and with 1/10,000 'Methysergide' (MS491 Sandoz), a serotonin blocking agent. Pretreatment of ileum strips with salicylate and atropine did not block the effect of irradiated serum, but salicylate and MS491 either blocked the response completely or markedly inhibited it. Because MS491 blocks not only serotonin but also histamine, a stronger antihistamine was tested.

In fifteen separate preparations pretreated with salicylate and chlortrimeton (1/1,000) the usual effect of irradiated serum was either totally or markedly blocked. Chlortrimeton also blocked the usual contractile response evoked by exposure of *in vitro* ileum preparations to X-ray (10 s at 1,000 r./min).

These findings strongly suggest that the aversion conditioning evoked by injection of serum from irradiated donors is caused by the effect of histamine on the gut. It also seems that the immediate transient contractile response of the gut to direct radiation exposure may involve the release of bound histamine, as indeed may the early phase of "radiation sickness".

Pituitary Growth Hormone Essential for Regulation of Serum Cholesterol

PITUITARY growth hormone was found to be essential in the normal regulation of the rat's serum cholesterol during a study of the cause(s) of the hypercholesterolaemia usually observed in the hypophysectomized rat.

To determine whether the hypercholesterolaemia occurring in the hypophysectomized rat was solely the result of impaired thyroid function, we first measured the serum cholesterol changes taking place in five groups of ten mature male rats (Long Evans strain) after (*a*) simple thyroidectomy (T), (*b*) thyroidectomy, castration and adrenalectomy (T–C–A); (*c*) removal of only the anterior lobe of the pituitary; (*d*) removal of only the posterior lobe of the pituitary; and (*e*) removal of both the anterior and posterior pituitary lobes. Following surgery, all rats (and also ten unoperated controls) were fed a liquid low-fat, low-cholesterol (40 mg/100 ml.) diet (55 ml. per day: an amount which corresponds to the average daily diet of normal rats). The rats were anaesthetized with ether and bled from the tail weekly.

Average serum cholesterol values (measured by the method of Martinek[1]) for the rats which were totally hypophysectomized (Fig. 1) rose progressively during the postoperative period. The value of 185 mg/100 ml. for

Enzymes in the Whatman tradition - purity and reliability

Whatman – already famous for the quality of their filtration and chromatographic materials – are now extending their field of operations to include enzymes and related biochemicals for all applications where purity and reliability are of high importance. The new Whatman range includes Lactate dehydrogenase, L-asparaginase, Elastase and Glyceraldehyde-3-phosphate dehydrogenase. They are all made to an extremely high standard of purity, and detailed specifications are given in the new Whatman Biochemicals' catalogue. The free loose leaf catalogue is now available and supplementary sheets will be sent to all catalogue holders as new products are introduced. Prices are extremely competitive.

Whatman – enzymes you can trust

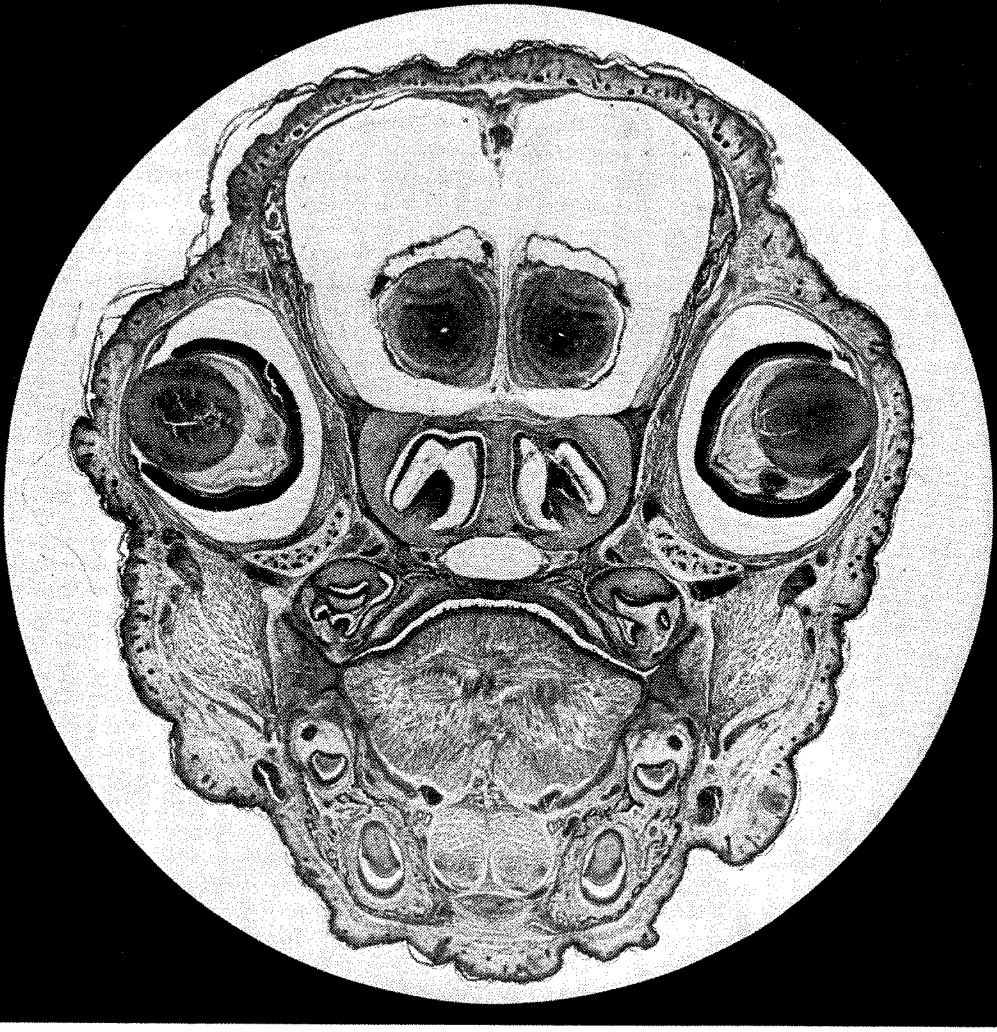
Take your classes down to microscopic size.



If you want to show a room-full of students what's going on under a microscope—instantly, clearly, and at several magnifications—the Zeiss Revolver Microprojector will do it for you. The mouse embryo illustrated above, showing the rudiments of the eyes, is an example of what can be shown. To change magnifications and go from an over-all view to successively smaller and more selective areas of your specimen, you simply revolve the nosepiece, bringing any of six objectives into play. Moreover, you can move the slide at any time to change the area under observation.
Two of the six objectives are the famous Zeiss LUMINARS, for low-power projection; the other four are PLANACHROMATS for magnifications up to 100X. All the objectives assure you a flat field, sharp from edge to edge. And a choice of four projection lenses lets you vary image diameters from about 3 ft. to 10½ ft. over projection distances of 10½ ft. to 65½ ft. The built-in multi-purpose illuminator takes either a CSI lamp or an XBO xenon lamp. The instrument is compact (35″ x 10½″ base; 19½″ high) and simple to operate.

rats subjected to removal of just the anterior lobe was, moreover, approximately the same at the end of 3 weeks as that (190 mg/100 ml.) for the total hypophysectomized rats. For rats subjected to removal of just their posterior lobe the value (68 mg/100 ml.) was approximately the same at the end of 3 weeks as that (72 mg/100 ml.) for controls. It seems that the hypercholesterolaemia in the totally hypophysectomized rats arose solely from the absence of the anterior lobe.

As Fig. 1 demonstrates, hypophysectomized rats differed from thyroidectomized rats in that serum cholesterol rose not only more quickly but also to a much higher value during the 3 week postoperative period. On the other hand, those rats which were not only thyroidectomized but also castrated and adrenalectomized failed to exhibit a higher average serum cholesterol than those which were only thyroidectomized. These results suggested that the higher serum cholesterol of the hypophysectomized rats was not the result of hypofunction of either the sex or adrenal glands which is known to occur after removal of the pituitary. It is evident, moreover, that neither the absence of ACTH nor the sex stimulating hormones in the hypophysectomized rat were concerned in the hypercholesterolaemia.

A second study further indicated that the hypercholesterolaemia of the hypophysectomized rat could not be attributed solely to thyroid hypofunction following the absence of thyroid stimulating hormone (TSH). Thus when ten thyroidectomized and ten hypophysectomized rats were administered relatively physiological amounts of TSH (in the form of 2 mg of thyroid substance daily) after surgery, whereas the average serum cholesterol of the thyroidectomized rats did not increase, that of the hypophysectomized rats rose to an average level of 120 mg/100 ml., a value significantly higher than that of the controls and thyroidectomized rats treated with thyroid substance (Fig. 1).

A third study confirmed that the deranged cholesterol metabolism of the hypophysectomized rats arose from something more than thyroid hypofunction. Thus when ten hypophysectomized, nine thyroidectomized and five normal control rats were injected intravenously with sodium ^{3}H-acetate and killed 1 h later, analyses of their liver and serum cholesterol revealed (Table 1) that the percentage of incorporation of tritium in newly synthesized hepatic or plasma cholesterol was far less in the hypophysectomized than in the thyroidectomized rats.

In a fourth experiment, we demonstrated that not only the cholesterol but also the triglyceride metabolism of the hypophysectomized rat differed from that of the thyroidectomized rat. Thus 12 h after the intravenous injection of 250 mg Triton[2] into ten hypophysectomized rats, ten thyroidectomized rats and ten controls, the rise in serum cholesterol and triglyceride (Table 2) was much less in the hypophysectomized rats than in the thyroidectomized rats. Clearly the hypophysectomized rats were discharging less cholesterol and far less triglyceride into their blood than the thyroidectomized rats[2].

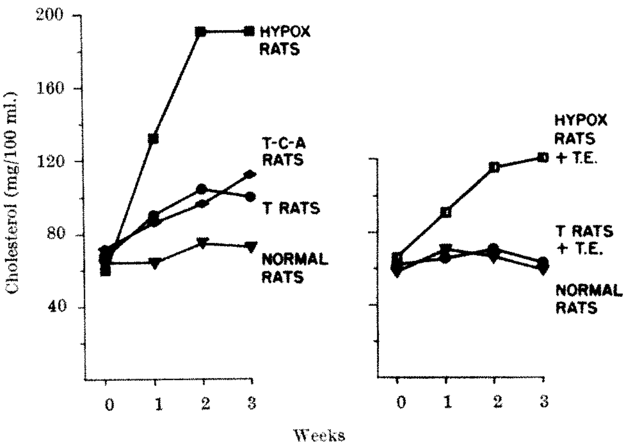

Fig. 1. Left: increase of serum cholesterol over 3 weeks in hypophysectomized (Hypox), thyroidectomized (T) and thyroidectomized-castrated-adrenalectomized (T-C-A) rats. Right: hypophysectomized (Hypox) rats given thyroid extract (T.E.) and thyroidectomized (T) rats given thyroid extract.

We concluded that hypercholesterolaemia taking place in the hypophysectomized rat was not the result solely of thyroid hypofunction and was probably totally independent of the sex and adrenal glands. The results also suggested that some other hormone of the pituitary anterior lobe besides TSH, ACTH, FSH and ICSH must be important in the regulation of serum cholesterol and that its absence leads to an increase in this sterol.

To identify this hormone, separate groups of male rats, immediately following extirpation of their pituitary glands, were given (*a*) ACTH (1 unit twice daily), (*b*) testosterone (0·5 mg three times a week), (*c*) thyroid extract (2 mg daily) and (*d*) purified bovine pituitary growth hormone (supplied by Dr C. **H.** Li, 100 µg three times daily). Normal and untreated hypophysectomized rats were also used. All rats were fed the low-fat, low-cholesterol liquid diet and were bled weekly to determine serum cholesterol concentration.

As Table 3 illustrates, neither the daily injection of ACTH nor the thrice weekly injection of testosterone altered the ensuing hypercholesterolaemia of the hypophysectomized rats. Thyroid extract—as was observed in the initial experiments—reduced but did not completely prevent the rise in plasma cholesterol of the hypophysectomized rats. Surprisingly, the administration of growth hormone was as effective as the thyroid extract in reducing the postoperative hypercholesterolaemia of the hypophysectomized rats.

In a second study, various combinations of the above hormones were administered to hypophysectomized rats. Groups of hypophysectomized rats were given (*a*) thyroid + ACTH + testosterone + growth hormone, (*b*) thyroid + ACTH + testosterone, (*c*) thyroid + growth hormone and (*d*) growth hormone + ACTH + testosterone, in the amounts already given. For control purposes, normal intact and untreated hypophysectomized rats and normal rats given both thyroid extract and growth hormone were observed. The animals were fed and bled as described.

* *S.E.* of mean.
† Mean is significantly different from corresponding value for control untreated hypophysectomized rats ($P < 0{\cdot}001$).
‡ Mean is significantly different from corresponding value for control untreated hypophysectomized rats ($P < 0{\cdot}001$) but essentially the same as that for control normal untreated rats.

The results again indicated that either thyroid or growth hormone could inhibit significantly the development of hypercholesterolaemia in the hypophysectomized rat. When thyroid was administered with ACTH, testosterone and growth hormone, hypercholesterolaemia was completely prevented in the hypophysectomized rat (Table 3). When thyroid was given with just ACTH and testosterone, however, the partial inhibition of the hypercholesterolaemia achieved was no greater than that from administration of thyroid alone (compare III-C with IV-A-1 in Table 3). But when growth hormone was given with thyroid, the onset of hypercholesterolaemia was completely prevented. When ACTH and testosterone were given with growth hormone, the degree of inhibition of hypercholesterolaemia was no greater than that with growth hormone alone (compare III-D and IV-B). In the normal intact rat, the combined administration of both thyroid and growth hormone (I-B) did not influence the normal cholesterolaemic state present in these rats.

The requirement not only of physiological doses of thyroid but also similar doses of growth hormone for the normal cholesterolaemic status adds to the evidence for the essential part of growth hormone in cholesterol regulation. The administration of either hormone singly or together to the normal intact rat did not, however, reveal this. Apparently the normal animal possesses sufficient of these hormones so that moderate additions of either of them led to virtually no change in plasma cholesterol.

Although the administration of growth hormone has long been known to alter the plasma fatty acid level in the experimental animal[3-5] and humans[6,7], its action in the regulation of serum cholesterol was obscured partially by the fact that it usually has been administered to normal animals and in such large doses that a diabetic state ensued[5]—a complication which might counteract any possible hypocholesterolaemic effects of growth hormone itself. Further, this complication is perhaps present in most acromegalic patients for they are usually studied only after the severity of their pituitary hypersecretion of growth hormone has induced a diabetic state, which again might obscure any hypocholesterolaemic effects of excess growth hormone. It is interesting in this connexion that Camitta and Gray[8] recently described a patient suffering from acromegaly with diabetic lipaemia and hypercholesterolaemia who promptly exhibited a relative hypocholesterolaemia after his diabetes was alleviated by insulin. Finally, although growth hormone reputedly has a biological life of more than 9 h (ref. 9), this value was based on the persistence of its growth-affecting rather than on its lipid-affecting properties. Consequently, to demonstrate its part in the regulation of plasma cholesterol, one may need to administer growth hormone frequently, as we have done.

This work was supported by grants from the National Heart Institute, the Burroughs–Wellcome Fund, and the Tarrant County Texas Heart Association. We thank Dr C. H. Li of the University of California for a generous supply of growth hormone and suggestions concerning this study.

Dietary Sucrose and Platelet Behaviour

WE have reported[1] that six out of a group of nineteen healthy young men responded to a diet rich in sucrose by an increase in body weight, in plasma insulin level and in platelet adhesiveness. From this experiment we have suggested that only some people are susceptible to "sucrose-induced hyperinsulinism" and that this may be associated with their susceptibility to occlusive atherosclerotic disease. A further study[2] of two groups of middle-aged men, one suffering from peripheral vascular disease and the other apparently free from arterial disease, supported this suggestion.

Platelet adhesiveness may well play an important part in atherogenesis, so we thought it worth while to study in more detail the effect of dietary sucrose on platelet behaviour. We have therefore examined the electrophoretic mobility of platelets, according to the technique of Hampton and Mitchell[3]. This technique is more precise than that for platelet adhesiveness; moreover, mobility and adhesiveness are likely to be related phenomena[4].

Hampton and Mitchell[3] showed that the mobility of platelets of apparently healthy persons is not much affected by low concentrations (0·005 μg/ml.) of adenosine diphosphate (ADP) or noradrenaline, but is considerably increased by concentrations of 0·05 μg/ml. On the other hand, the mobility of platelets of persons with atherosclerosis is increased by the lower concentration of ADP but very little affected at the higher concentration of ADP, while the mobility in the presence of noradrenaline is the same as that of platelets from healthy persons.

We have studied three subjects previously shown to develop sucrose-induced hyperinsulinism, and three subjects shown not to do so. There were two men and one woman in each group. All seemed to be healthy by clinical examination, and showed no abnormalities in a twelve-lead electrocardiogram. After 5 days of preliminary study, including measurement of diet, they were told to substitute sucrose for starch in their diet as much as possible for the next 2 weeks, and then to revert to their normal diet. Before the beginning of the high sucrose diet, at its completion, and 2 weeks after its completion, the subjects were weighed and venous blood taken for determination of blood glucose[5], plasma insulin by immuno-assay[6] and platelet mobility[3]. The latter technique involves making a concentrated suspension of platelets by mixing one part of "platelet-rich plasma" (PRP) with nine parts of "platelet-poor plasma" (PPP). The PRP fraction is obtained by slow centrifugation of citrated blood, and careful collection of the layer just above the red and white cells; the PPP fraction is obtained by subsequent high speed centrifugation and collection of the supernatant plasma.

All six subjects behaved as they had in previous investigations. The three who had shown sucrose-induced hyperinsulinism did so again; the insulin concentrations and the body weights had increased significantly by the end of 14 days on high sucrose diets, and had fallen again at the end of the next 14 days on normal diets (Table 1). The remaining three subjects, who had not shown these changes previously, also failed to show them in this study.

At the beginning of the study, the platelet mobility of both groups of subjects was the same, and similar to that of normal people[3] (Fig. 1). At the end of the period of the high sucrose diets, however, the mobility was changed in the subjects with hyperinsulinism, but not in the other subjects. In the former, the mobility was similar to that found in atherosclerosis; maximal mobility with ADP occurred when this substance was present in the lower concentration of 0·005 μg/ml. (Fig. 2). After 14 days on normal diets, the behaviour of the platelets of these subjects had partly, but not completely, reverted to the "normal" behaviour seen at the beginning of the experiment (Fig. 3).

Bolton *et al.*[7] have shown that the abnormal platelet behaviour can be transferred to "normal" platelets by

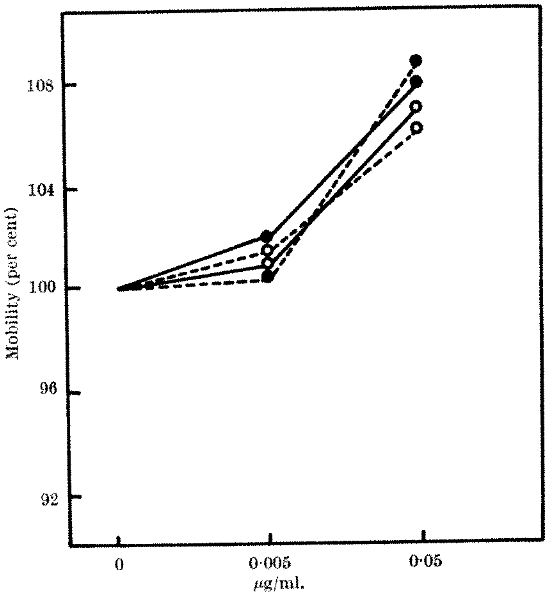

Fig. 1. Mean platelet electrophoretic mobility in presence of ADP (●) or noradrenaline (○), before sucrose diet. ———, Three subjects who later developed hyperinsulinism after sucrose; - - -, three subjects who did not develop hyperinsulinism.

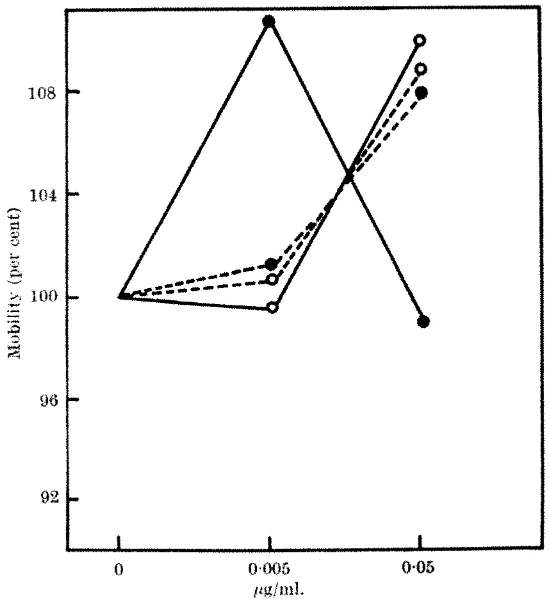

Fig. 2. Mean platelet electrophoretic mobility in presence of ADP (●) or noradrenaline (○), after 14 days on high sucrose diet. ———, Three subjects who developed hyperinsulinism; - - -, three subjects who did not develop hyperinsulinism.

Table 1. EFFECT OF HIGH-SUCROSE DIET IN SIX SUBJECTS (MEAN VALUES)

Diet	Group 1						Group 2					
	kcalories per day	Weight (kg)	Sucrose (g/day)	Insulin (μU/ml.)			kcalories per day	Weight (kg)	Sucrose (g/day)	Insulin (μU/ml.)		
				0	30 min	120 min				0	30 min	120 min
Normal	3,050	69·7	142	23	67	36	3,230	73·1	150	22	68	34
High sucrose	3,130	71·9	427	28	135	80	3,350	73·6	418	21	69	33
Normal	—	69·6	—	24	71	39	—	73·3	—	23	70	34

Group 1, three subjects previously shown to develop "sucrose-induced hyperinsulinism".
Group 2, three subjects previously shown not to develop "sucrose-induced hyperinsulinism".
Insulin measured before and at intervals of 30 min and 120 min after 50 g of glucose orally.

the plasma from subjects with atherosclerosis. This was also true of the behaviour of the platelets in our subjects with sucrose-induced hyperinsulinism. When the plasma (PPP) from these subjects, at the end of 14 days of high sucrose intake, was added to the platelets (PRP) from the other subjects, the mobility with ADP was changed to that characteristic of "abnormal" platelets (Fig. 4).

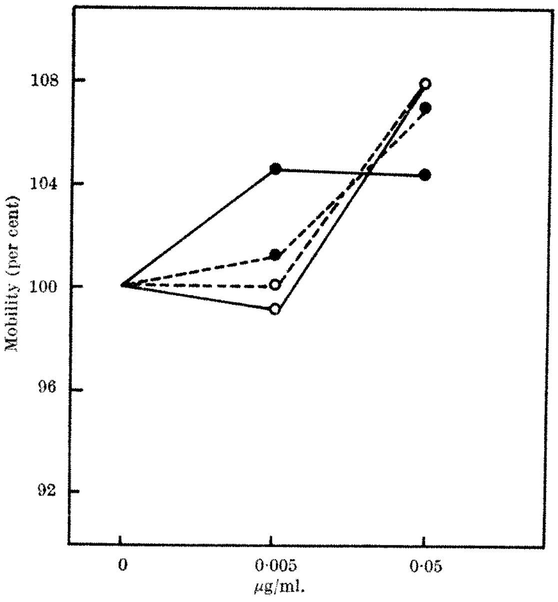

Fig. 3. Mean platelet electrophoretic mobility in presence of ADP (●) or noradrenaline (○), 14 days after completion of high sucrose diet. ———, Three subjects who had developed hyperinsulinism; - - -, three subjects who had not developed hyperinsulinism.

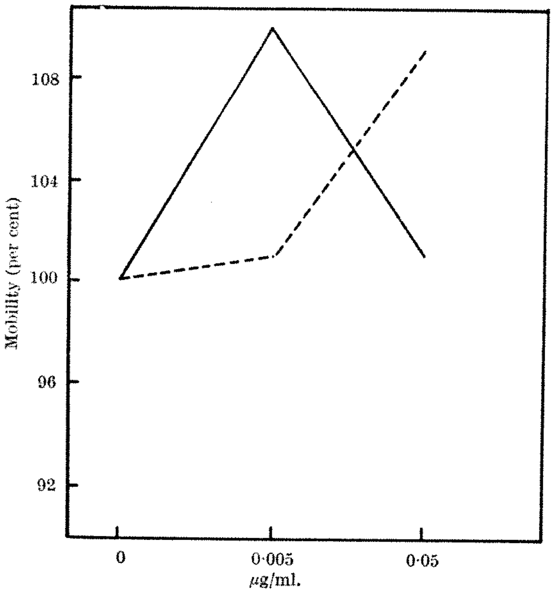

Fig. 4. Effect of ADP on "normal" platelets (PRP) suspended in "normal" or in "abnormal" plasma (PPP). Mean of three subjects. ———, Normal platelets in abnormal plasma; - - -, normal platelets in normal plasma.

We considered the possibility that the abnormality produced by dietary sugar was a direct result of the higher level of insulin in the plasma, but this was unlikely, for after 2 weeks on normal diet the hyperinsulinism induced by sucrose had virtually disappeared, while a fair degree of platelet abnormality was still seen (Table 1, Fig. 3). Nevertheless, we measured platelet mobility in the presence of 200 μU/ml. of porcine insulin, and found that it was quite unaffected.

We thank the British Heart Foundation for financial support.

Effect of Early Malnutrition on the Reaction of Adult Rats to Aversive Stimuli

A GREAT deal of interest has been shown in the relationship between early malnutrition, especially protein–calorie malnutrition, and intellectual capacity or learning ability. But early malnutrition may cause other changes in behaviour. An animal's motivation for food or water may be affected if it is deprived of them in early life[1–4]. In a non-appetitive situation Barnes *et al.*[5] noted a "motivational and emotional" difference in previously malnourished rats in learning a water maze. Moreover, adult pigs which had been fed protein-poor diets early in life and then given a full diet took longer to extinguish a conditioned avoidance response than controls, although there was little difference in the rate of acquisition of the response[6]. This has also been reported in rats when there was more intertrial responding in previously malnourished animals[7]. We have investigated whether a brief period of malnutrition very early in life increases the emotional reactivity of the adult to aversive stimulation.

Holtzman rats were distributed in litters consisting of eight pups to a dam. During suckling, half the dams were given a purified diet containing 21 per cent protein (as 25 per cent casein) and the rest were given diets containing 10 per cent protein (as 12 per cent casein) to restrict the availability of milk during the pre-weaning period. All pups were allowed to nurse for 3 weeks, and then the males were taken for further study. These animals were fed a purified diet containing either 21 or 2·5 per cent protein (as 25 and 3 per cent casein respectively) for the next 4 weeks, after which all animals received the 21 per cent protein diet. The behavioural tests started when rats were about 16 weeks old. Three tests were performed, each with different animals.

First we used a modified open field apparatus, a large wooden box (27·0 × 34·5 × 45·5 cm), open on top with a 'Plexiglas' front. The bottom was marked with six squares. In three 10 min sessions the animals became adapted to the apparatus. For the fourth session they were placed in the apparatus as usual, but half-way through the session a 28 V solenoid attached to the rear of the chamber was activated to make a loud, sharp noise. The amount of locomotor activity (number of squares crossed) before and after the noise was recorded.

In the second test we examined the effect of early malnutrition on passive avoidance behaviour. The animal was placed on a small (12·7 × 7·6 cm) platform which was elevated 7·6 cm from an electrified grid floor. Immediately after the animal stepped off the platform it received a 0·8 mA electric shock for 0·5 s. The animal was returned to its home cage for 60 s and then replaced on the platform. The time taken to leave the platform was then recorded (although after 5 min the animal was removed).

In the last behavioural test of this series we investigated whether previously malnourished rats would avoid an electric shock more actively than others. The animals were placed in a small compartment and required to press a bar to postpone a brief electric shock (1 mA lasting 0·5) for 20 s (S—S = R—S = 20). The animals were given five sessions lasting 165 min.

Fig. 1 shows growth patterns during the experiment. The restriction of protein both before and after weaning had a significant effect ($P < 0{\cdot}001$) on the rate of growth and the final weight—the less protein the smaller the animal.

Table 1. RESULTS OF BEHAVIOURAL TESTS AND EXPERIMENTAL CONDITIONS

Pre-weaning diet: Post-weaning diet:	Control Control	Restricted Control	Control Restricted	Restricted Restricted
Test 1 (per cent locomotor reduction)	$56{\cdot}0^a$ (7)	$51{\cdot}8^a$ (7)	$65{\cdot}5^b$ (7)	$74{\cdot}3^c$ (7)
Test 2 (reciprocal latency)	$0{\cdot}095^a$ (7)	$0{\cdot}020^b$ (7)	$0{\cdot}052^b$ (7)	$0{\cdot}020^c$ (7)
Test 3 (bar press per min)	$3{\cdot}97^a$ (8)			$5{\cdot}59^b$ (8)

Values within a row not designated with the same letter are statistically significant ($P < 0{\cdot}01$).
The numbers of animals in each group are shown in parentheses.

The results of the behavioural tests are given in Table 1. The typical response to the noise in the first experiment was first to run to a corner, crouch and show considerable signs of emotional stress—defaecation and urination. Later this response waned, but the animals usually remained fairly close to the corner and further exploration of the box was inhibited. The scores represent the percentage reduction of motility (number of squares crossed in the last 5 min compared with the 5 min before the noise) after the activation of the solenoid. Clearly, rats that had been malnourished by receiving the 2·5 per cent protein diet made a greater response to the noise than the control rats. Moreover, pre-weaning restriction of protein was not itself sufficient to alter the response in this measure.

Rats tested for passive avoidance responded according to the same pattern, and the animals malnourished in early life made a significantly greater passive avoidance response than controls, as their longer time on the platform shows. This test revealed a significant effect of pre-weaning restriction of protein. There were no differences in the initial delay when the animals left the platform.

Not only did the animals malnourished early in life react more intensely to an aversive stimulus, but they responded faster in the Sidman avoidance situation, as the results of the third test show (Table 1). Another measure recorded in the Sidman avoidance situation, but not shown in Table 1, was the time for which the bar was depressed. This measure also reflected the greater response of these animals to the aversive conditions.

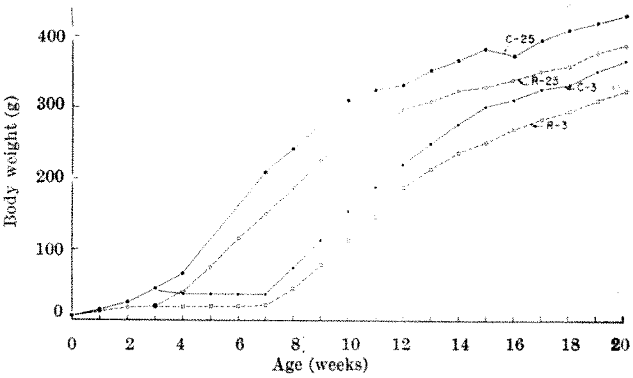

Fig. 1. Growth curves of rats malnourished early in life. C, Rats suckled by dams given 25 per cent casein (control pre-weaning); R, rats suckled by dams given 12 per cent casein; 25, rats on a diet containing 25 per cent casein during the first 4 weeks after weaning; 3, rats on a diet containing 3 per cent casein during the first 4 weeks after weaning.

When casually observed in their home cage, rats that have been malnourished are not distinguishable from the controls apart from being smaller. The behavioural difference becomes apparent only when they are placed in a moderately stressful situation. This suggests that one effect of malnutrition during early development is to produce a rather long lasting, if not permanent, lowering of the threshold of the stress–response system. There may be some support for this idea in the finding that the adrenals of early malnourished animals are consistently larger than in controls. Several workers have suggested that adrenal–pituitary secretions play a part in the behavioural response to stress[8-10].

It is not yet clear whether early malnutrition results in deficient learning ability[11,12]. The data presented here, however, suggest that severe malnutrition experienced very early in life results in other long lasting, if not permanent, behavioural abnormalities.

Spread of Responses in the Cerebral Cortex to Meaningful Stimuli

THE primary visual receiving area of the mammalian cerebral cortex is readily excited by sudden alterations in the intensity of light falling on either retina. Techniques developed by Hubel and Wiesel[4] have made it possible to record the responses of individual cortical neurones to appropriately placed retinal stimuli of the right shape. The response of single units to the proper form of physiological stimulus is sometimes so clear that a single flash or movement of a pattern of light in the visual field will invariably produce a burst of discharges from the recorded neurone. Most neurones in the lightly anaesthetized or unanaesthetized visual cortex, however, are less predict-

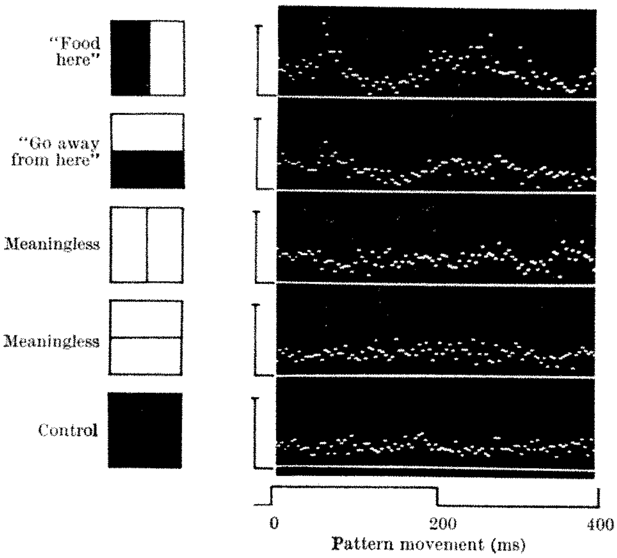

Fig. 1. Post-stimulus histograms obtained from a single cell (cat *A*, cell 1) in the anterior contralateral supra-sylvian gyrus in response to the various patterns shown. Ordinate, count/4 ms × 600. Recording time, 4 min. Pattern movements were at right angles to the pattern border.

able in their behaviour, and their response to retinal excitation is best demonstrated by averaging procedures[2]. A post-stimulus histogram (PSH) is obtained, which displays the number of neuronal discharges occurring at various times after each of a series of identical retinal stimuli. Thus the PSH indicates the distribution of probability of unit discharge, following visual excitation.

We have found that, in the cat, the responses of cortical neurones lying outside the primary receiving area are extremely weak, so that it is often impossible to produce any detectable response from neurones in unanaesthetized parietal cortex. This fact is not altogether surprising, for an intact animal would not be expected to pay the least attention, or to respond in any way, to the sort of patterns projected on the retina during physiological experiments. To the intact animal such patterns would be "meaningless". On the other hand, a more widespread cortical response to retinal excitation with "meaningful" patterns might be expected; this would have produced some predictable motor response from the intact animal. We have therefore begun a series of experiments designed to compare the spread, outside the visual area, of responses to "meaningful" and "meaningless" patterns presented in the visual field.

Cats were trained to respond to simple geometrical patterns by teaching them to choose between two possible sources of food on the basis of the pattern displayed. In this way, they learned that one pattern meant "food here", and the other meant "go away from here or you will get a mild shock". When an animal was trained to 80–90 per cent efficiency, it was anaesthetized with volatile anaesthetic and the forebrain was neurologically isolated from the rest of the nervous system without damage to its blood supply[1]. Artificial respiration was supplied and, after the operation, the preparation was taken off anaesthetic. This procedure produces an unanaesthetized brain with no motor outputs and only one functional input—the visual pathway. Despite surgical interference, the cortical neurones still display spontaneous activity and the units in the primary visual area respond to retinal excitation in a manner very similar to that seen in the lightly anaesthetized animal. To excite the visual system, we projected patterns on a pearl-glass screen about 30 cm in front of the cat. These patterns were focused on one retina by a 10 dioptre lens and were provided with a rectangular oscillation of approximately 30 s arc and 3 c.p.s. frequency[3]. An averaging computer was used to record the probability of unit discharge at various times after the two movements of the stimulating pattern. We excited the retina with two classes of pattern: (*A*) "meaningful" patterns which produced predictable motor responses in the trained animal: (*B*) similar patterns which the animal had not seen before ("meaningless"). All these were patterns which, in our experience, produce approximately equal excitation of cells in primary visual area.

Table 1. RELATIVE MAGNITUDE OF RESPONSES TO MEANINGFUL AND MEANINGLESS PATTERNS

			Patterns listed in order of magnitude of response			
Cortical area	Cat	Cell	Greatest	....	....	Least
Parietal	*A*	1 (Figure)	+	+	○	○
		2	+	+	○	○
		3	+	+	○	○
	B	1	+	+	○	
		2	+	○	+	
		3	+	○	+	
	C	1	+	+	○	
		2	+	+	○	
		3	+	○	+	
Auditory	*B*	4	+	○	+	
		5	+	○	+	
Sensori-motor	*A*	4	+	+	○	○
		5	+	○	○	+
	C	4	+	+	○	
Percentage of meaningful patterns in column			100	54	39	10

+, Meaningful patterns: "food here" or "go away from here". ○, Meaningless patterns. Brackets indicate equal response.

Fig. 1 shows five post-stimulus histograms obtained from the same cell in the "parietal" area (anterior part of the contralateral supra-sylvian gyrus). The first four histograms show responses to the various patterns indicated. The fifth represents a control, recorded with the projector lamp switched off, but the rest of the apparatus active; this indicates the sampling error to be expected. It is clear that the two meaningful patterns produced a greater disturbance of the neurone's behaviour than did the two meaningless patterns. We have obtained similar results from fourteen cells in three cats. These results are summarized in Table 1. Response magnitude was assessed visually in terms of the amount of deviation from a horizontal line, taking into account the sampling error to be expected. The first column of the table contains only meaningful patterns, with the meaningless patterns in the second and third columns (only cat *A* was tested with two forms of meaningless stimulus). It would clearly be dangerous to base generalizations on such a small number of experiments, but we feel that these preliminary results were of sufficient interest to be reported.

Subcellular Localization of Serotonin in an Identified Serotonin-containing Neurone

KNOWLEDGE of the subcellular localization of serotonin (5-hydroxytryptamine) in neurones is important for an understanding of the precise physiological role of this amine in nervous tissue. Some of the most pertinent pharmacological and electrophysiological data on the neuronal role of serotonin have been obtained from work with molluscs[1,2]. In particular there is strong evidence that the amine acts as a transmitter on one particular type of neurone in the gastropod brain[2]. Fractionation studies with homogenates of bivalve ganglia, which are extremely rich in serotonin, have shown that the amine is bound to particles, but associated with particles of different density from those binding acetylcholine[3]. The precise type of particle or particles associated with serotonin, however, is not definitely known[4].

In the ganglia of gastropod molluscs are very large neurone somata, some of which contain amines[5]. We have examined in detail one particularly large serotonin-containing neurone, which is readily located in different preparations, in each cerebral ganglion of the slug *Limax maximus*. Results of the experiments show that serotonin is bound within small granulated vesicles of 40 to 100 nm in diameter and also, in certain conditions, in particles which resemble lysosomes.

Using standard methods of amine-fluorescence histochemistry[6], a giant yellow-orange fluorescing neurone was observed in each metacerebral ganglion of *Limax maximus*. The fluorescence was judged specific for serotonin using the usual criteria of colour, reducibility, fading and absence without paraformaldehyde sublimation. After the yellow fluorescence had faded, no green fluorescence indicative of catecholamines was observed.[7] A group of small brilliantly green fluorescing cells close to each giant cell provided convenient material for comparison. Reserpine, injected in amounts of 0·1 to 1 mg during 24 to 48 h, greatly reduced or abolished the fluorescence. Further evidence for the presence of serotonin and absence of catecholamines was provided by the effects of different drugs on the fluorescence and by bioassay of individual cells.

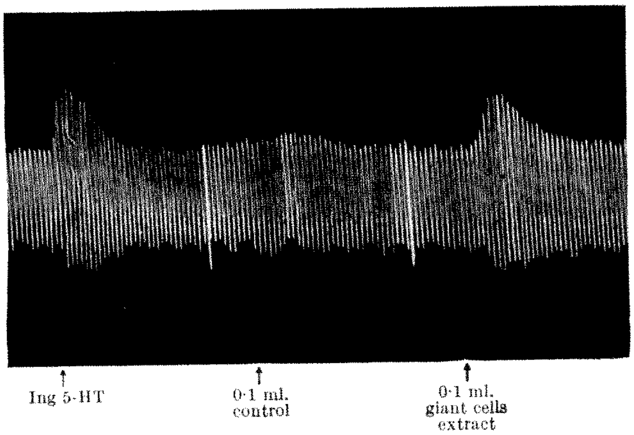

Fig. 1. Responses of an isolated heart of *Helix pomatia* to serotonin (5-HT), to an extract prepared from individually isolated giant serotonin cells and to a similarly prepared extract of an equivalent number of non-fluorescing cells (control).

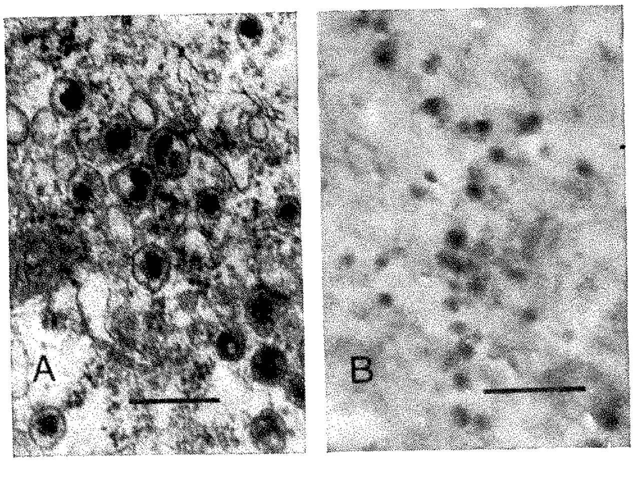

Fig. 2. *A*, Small group of granular vesicles in a giant serotonin cell fixed in glutaraldehyde and osmium and stained with lead citrate and uranyl acetate. (The bar represents 0·2 μm.) *B*, Electron dense deposits, representing sites of amine localization, in a giant serotonin cell. Tissue was processed by Wood's method[12]. The deposits are the same size as the granule centres in *A*. (The bar represents 0·5 μm.)

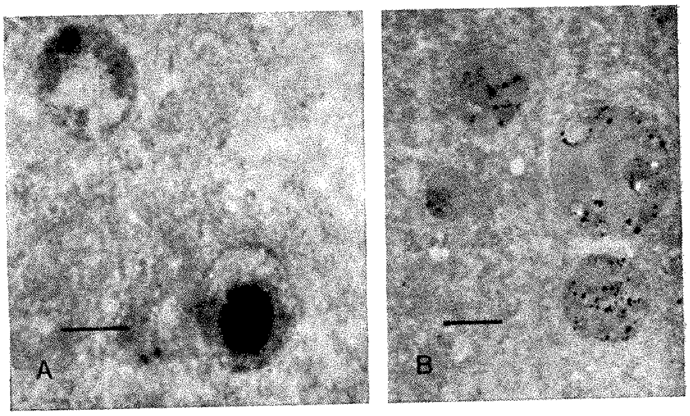

Fig. 3. Staining, indicative of an amine, in particles which resemble lysosomes in the giant serotonin cell. *A*, Tissue fixed and stained by Wood's method[12]. (The bar represents 0·5 μm.) *B*, Tissue processed by the method of Cannata *et al.*[15]. (The bar represents 1 μm.)

The intensity of yellow fluorescence was reduced by injecting *p*-chlorophenylalanine, which blocks serotonin formation[7], though not altered with α-methyl-*m*-tyrosine, an inhibitor of tyrosine hydroxylase[8]. Injections of the precursor of serotonin, 5-hydroxytryptophan, increased the intensity of fluorescence, but there was no change after injecting the catecholamine precursor 3,4-dihydroxyphenylalanine.

Isolated cells were assayed on the heart of *Helix pomatia*, a preparation known to be remarkably sensitive to serotonin but insensitive to catecholamines[9]. Control extracts were prepared from the same number of neurone somata of a similar size, which did not fluoresce. Giant metacerebral cell extracts increased the amplitude and frequency of heart-beat in a manner indistinguishable to that produced by serotonin whereas control extracts had no effect (Fig. 1). Bromo-lysergic acid diethylamide antagonized the effect of the giant cell extract as well as that of serotonin. These experiments provided strong independent evidence for the presence of serotonin in the metacerebral cells. On the basis of other experiments made on closely related species[10] and on the sensitivity of *Helix* hearts to different agents[9], we concluded that there is no substance other than serotonin which could have accounted for the pharmacological effect, certainly not dopamine, noradrenaline or adrenaline. From the results of seven assay experiments, the serotonin content was estimated as 0·7 ng/cell. The total volume of the giant cell is about 1·3 nl, but about one-fifth of this is occupied by the nucleus, which does not fluoresce. Thus the concentration of serotonin in the cytoplasm of the cell soma is 4×10^{-3} M.

Electron microscopy of the cell revealed the presence of large numbers of vesicles with irregular granular cores (Fig. 2*A*), together with elongated mitochondria, particles resembling lysosomes and other inclusions previously reported in molluscan neurones[11]. Ganglia removed from slugs during the summer months and fixed and processed by the method of Wood[12] for detecting amines contained electron dense reaction products in the small granules of the serotonin-containing cell (Fig. 2*B*). Prior injection of reserpine greatly reduced the number of granules in the serotonin-containing cell. The histochemical method has been shown to be specific for amines in molluscan tissues[9]. We therefore concluded that serotonin is sequestered within the small granules. The granules have similar dimensions to those which were suggested to bind primary catecholamines and serotonin in the nerves of the snail heart[9] and catecholamines in bivalve ganglia[13] and also to the granules of the Retzius cell of one leech, which are considered to bind serotonin[14].

Tissue studied earlier in the early spring of this year provided evidence for an additional site of binding of serotonin. At this time, preparations stained for the ultrastructural localization of amines showed dense reaction products in certain irregular areas of the particles resembling lysosomes (Fig. 3). In post-osmicated tissue, areas of the "lysosomes" also appeared extremely electron dense. After treatment with reserpine, dense staining was only rarely observed in tissue processed by the two histochemical methods used. It therefore seems that in some conditions as yet insufficiently specified, but perhaps associated with the season, serotonin may also be associated with particles which resemble lysosomes in these neurones. In connexion with this observation we have repeatedly noted in tissue fixed and stained by standard methods the occurrence of small granulated vesicles in the "lysosomes" of the giant serotonin cells.

It is interesting to note that the serotonin-containing neurones described here are homologous to the *Helix* metacerebral neurones which exhibit marked anomalous rectification[16]. We have observed that these *Helix* cells also contain serotonin in about the same concentration as those of *Limax*.

Annual Production and Respiration in Animal Populations

ENGELMANN[1] has examined the relationship between annual production and annual respiration in kilocalories per m² per year for terrestrial animal populations. We have re-examined this relationship in the light of a large number of further studies, taking into account aquatic and marine animals not considered by Engelmann and correcting a number of minor errors in his article, and we have tried to explain several features of the relationship in terms of the life histories of the species investigated.

We have used the following terminology[2]: $R =$ annual population respiration, $P =$ annual population production (including somatic growth, eggs and exuvia), $R + P = A =$ annual population assimilation; all expressed as kilocalories per m² per year.

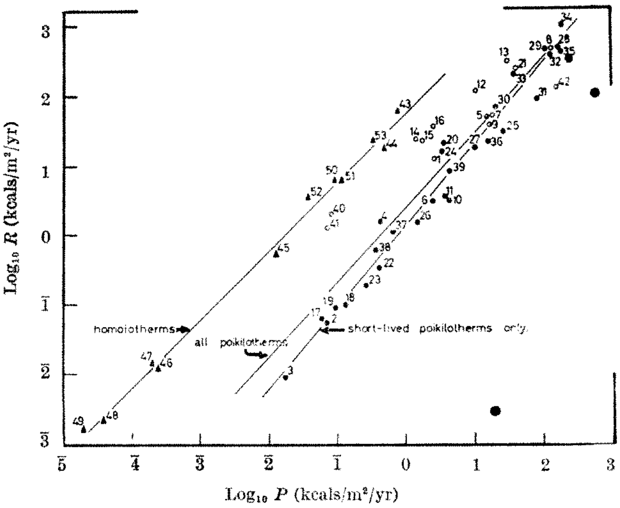

Fig. 1. The relationship between annual production (P) and annual respiration (R) (kcalories/m²/yr) in animal populations. The numbers associated with each point correspond to the numbers in the first column of Table 1. ▲, Homoiotherms; ○, long-lived poikilotherms; ●, short-lived poikilotherms.

The data reviewed are presented in Table 1. We have omitted those studies that assume *a priori* P/R ratios (for example, data on nematodes and *Prokelisia* included by Engelmann), and "old field" data on *Philaenus*[21] in which R was greatly inflated by immigration of adults; also omitted are data on the ant *Pogonomyrmex*[30] shown by Engelmann to be atypical, and data on the planarian *Phagocata*[19], which includes large quantities of mucus in the estimates of P. Data from Table 1 are plotted in Fig. 1. (Note that data on *Passerculus* and *Mustela*, plotted incorrectly by Engelmann, have been corrected.)

Because direct and independent field measurements of P and R are impossible, both these parameters are usually calculated by multiplying data on individual production and respiration respectively by estimates of population numbers or biomass. It may therefore be argued that P and R, when estimated in this way, are not statistically independent variables. Nevertheless, we believe that the empirical relationships between P and R obtained by normal regression techniques are of sufficient interest to justify their use.

Because respiration in the absence of living tissue is impossible, Fig. 1 shows $\log_{10} R$ as ordinate plotted against $\log_{10} P$ as abscissa. Strictly, however, R is a function of population biomass (that part of production which, temporarily, persists) rather than population production *per se*, and it is also practically useful and theoretically possible to consider P as a function of R. Consequently, in analysing the relationship between P and R, two equations are presented at each step, one with R and the other with P as the dependent variable.

The following least squares regression equations were calculated:

For poikilotherms, $\log R = 1{\cdot}0733 \log P + 0{\cdot}3757$ (1)

The slope of this line does not differ significantly from 1·0 (t_{40} 1·1899).

Alternatively, $\log P = 0{\cdot}8233 \log R - 0{\cdot}2367$ (2)

The slope of this line differs significantly from 1·0 (t_{40} 3·7405***).

For homoiotherms, $\log R = 0{\cdot}9812 \log P + 1{\cdot}7418$ (3)

The slope of this line does not differ significantly from 1·0 (t_9 0·7866).

Alternatively, $\log P = 1{\cdot}0137 \log R - 1{\cdot}7761$ (4)

The slope of this line does not differ significantly from 1·0 (t_9 0·5548).

Confidence intervals (95 per cent) were calculated for these regressions[31]. For poikilotherms (equation 1) between $\log P = -2\cdot0$ and $\log P = +2\cdot0$ these were $\pm0\cdot9136$ to $\pm0\cdot9698$; for poikilotherms (equation 2) between $\log R = -2\cdot0$ and $\log R = +3\cdot0$, $\pm0\cdot7997$ to $\pm0\cdot8507$; for homoiotherms (equation 3) between $\log P = -5\cdot0$ and $\log P = 0\cdot0$, $\pm0\cdot3150$ to $\pm0\cdot3338$; and for homoiotherms (equation 4) between $\log R = -3\cdot0$ and $\log R = +2\cdot0$, $\pm0\cdot3202$ to $\pm0\cdot3849$.

Part of the large scatter observed in the poikilotherm data (equations 1 and 2) may be explained in terms of life histories; further examination of the poikilotherm data suggests that populations of species known to be long lived can be distinguished from species with shorter generation times. An arbitrary age of two years was selected, and those poikilotherm populations in which a proportion of individuals were known to exceed two years of age (long-lived poikilotherms) were distinguished from those populations in which all the individuals were less than two years of age (comparatively short-lived poikilotherms) (Fig. 1). Two further regression lines were calculated for the comparatively short-lived poikilotherms

$$\log R = 1\cdot1740 \log P + 0\cdot1352 \qquad (5)$$

$$\text{and } \log P = 0\cdot8262 \log R - 0\cdot0948 \qquad (6)$$

The slope of both these lines now differs significantly from 1·0 (equation 5 t_{27} 4·3762*** and equation 6 t_{27} 6·2116***) and the 95 per cent confidence limits within the range of values of $\log P$ and $\log R$ given above all poikilotherms are reduced to $\pm0\cdot5140$ and $\pm0\cdot5544$ for equation 5 and $\pm0\cdot4312$ and $\pm0\cdot4598$ for equation 6; a considerable improvement.

The data do not justify similar regression calculations for long-lived poikilotherms, because less information is available and points 40 and 41 therefore have an unduly large influence on the regression lines. Nevertheless, it is clear from Fig. 1 that respiratory costs at any level of production tend to be higher in long-lived poikilotherms (where a standing crop of older individuals is maintained from year to year) than in short-lived poikilotherms. The inclusion of both groups in equations 1 and 2 greatly increases the scatter in the relationships between $\log P$ and $\log R$. It should be noted that our distinction between short and long-lived poikilotherms is purely arbitrary, and when further data become available it should be possible to quantify the influence of age in a more satisfactory manner. Several of the long-lived poikilotherms distinguished in this report, for example, are fish (points 12–16), individuals of which may be very long-lived and hence show the influence of age in an extreme form.

From the equations we have derived, it is possible to calculate mean net population production efficiencies,

$$\left(\frac{P \times 100}{A}\right)$$

* Long-lived poikilotherms (see text).

† Comparatively short-lived poikilotherms with low respiratory cost resting stages (see text).

The remaining poikilotherm species listed are comparatively short-lived poikilotherms with high respiratory cost non-productive stages (see text).

For homoiotherms (equations 3 and 4), b does not differ significantly from 1·0 and mean net population production efficiencies are approximately constant for all levels of production, varying only between 1·4 and 1·8 per cent. For poikilotherms in general (equations 1 and 2) the situation is less clear. In equation 1, plotting log R against log P, b does not differ significantly from 1·0 but, in equation 2, plotting log P against log R (because of the greater variability in values of R relative to values of P), b does differ significantly from 1·0. Both slopes for comparatively short-lived poikilotherms (equations 5 and 6) differ significantly from 1·0, however, and give virtually identical regression lines. For these comparatively short-lived poikilotherms, mean net population production efficiencies therefore increase markedly at lower production levels (Table 2). Two possible explanations can be suggested, and these are not necessarily mutually exclusive: populations of comparatively short-lived poikilotherms, in which total annual production is for some reason restricted at a low level may tend to maximize production efficiencies, in an attempt to compensate for this restriction or, alternatively, the apparent variation in mean net population production efficiency may be caused by differing life histories. Most comparatively short-lived poikilotherms, below log $P = 0$, overwinter as eggs; respiration during such resting periods is therefore reduced to a minimum. Most of the comparatively short-lived poikilotherms, above log $P = 0$, overwinter as juveniles or adults, and therefore respiration continues at a relatively high level when production is virtually zero.

Table 2. MEAN NET POPULATION PRODUCTION EFFICIENCIES FOR SHORT-LIVED POIKILOTHERMS, CALCULATED FROM EQUATION 5

Production P	Respiration R	Assimilation A $(P+R)$	Net population production efficiency $\frac{P}{A} \times 100$
	(kcalories/m²/year)		(per cent)
0·01	0·006125	0·016125	62
0·1	0·09145	0·19145	52
1·0	1·366	2·366	42
10·0	20·38	30·38	33
100·0	304·2	404·2	25

It may therefore be possible to recognize three types of poikilotherm; comparatively short-lived poikilotherms, which show low respiratory cost resting stages, in which annual population production efficiencies are high; comparatively short-lived poikilotherms, which show high respiratory cost non-productive stages, in which annual population production efficiencies are intermediate; and long-lived poikilotherms where a proportion of the population is in excess of two years old and probably experiences at least two high respiratory cost, non-productive periods; here, annual population production efficiencies are low.

"Life history effects" are not apparent for the limited homoiotherm data reviewed, because such effects are probably masked by the high respiratory cost of homoiothermy.

Apart from attempting to explain several features of the relationship between annual production and annual respiration in animal populations, the results may also prove to be of considerable practical value. There is increasing need in ecology for short cut methods for analysing the trophic-dynamics of complex communities, and these relationships, despite their large confidence intervals, may prove useful in predicting total energy flow through populations in which either P or R is known.

Pleistocene South-east Asiatic Pygmy Stegodonts

During the past fifteen years a series of Pleistocene pygmy stegodont elephants have been described from the Malay Archipelago. These forms are equal in importance and evolutionary interest to the classic examples of dwarfed insular elephants of the Mediterranean that have been known for more than a century[1], and so a brief account of their characteristics may be useful.

The best known Asiatic species of the genus *Stegodon* (a Plio-Pleistocene elephantid from Asia and Africa) is *Stegodon trigonocephalus* Martin from Java. The wealth of material of this species collected by Dubois during the last decade of the nineteenth century shows to advantage the amount of individual variation within a single species[2]. The unworn molars of this species of *Stegodon* are from a half to two-thirds as high as wide.

Stegodon hypsilophus Hooijer[3], probably confined to the Early Mid-Pleistocene Djetis Beds of Eastern Java, is characterized by the great relative height of its molar crowns as well as by its small size; as Table 1 shows, the height of M^3 is not less than that in *Stegodon trigonocephalus* but the width is rather less, resulting in a high height/width index (height : width × 100).

Table 1. MEASUREMENTS AND INDICES OF VARIOUS SPECIES OF *Stegodon*

	S. trigonocephalus		*S. hypsilophus*	*S. timorensis*
M^3	Java	Flores	Java	Timor
Width	76–113	77	64	51
Height	49–59	55	57	48
H/w index	46–68	71	89	94
	trigonocephalus		*sompoensis*	*timorensis*
M_3	Java	Flores	Celebes	Timor
Width	68–98	72	60	42
Height	48–61	50	40	37
H/w index	56–66	69	67	88

Measurements are in mm.

The first dwarfed stegodont to be found in the island of Flores[4] is on average only slightly smaller than *Stegodon trigonocephalus* from Java, and its molar crowns are just a little higher. This form has been considered distinct from the Java form at the subspecies level only: *Stegodon trigonocephalus florensis* Hooijer.

Several years later[5] another pygmy stegodont was found in Flores, with milk molars half as long and wide as those in the Java *Stegodon trigonocephalus*. Meanwhile, a *Stegodon* from the Pleistocene of the island of Celebes, associated with a very primitive archidiskodont elephant, was named *Stegodon sompoensis* Hooijer after its type locality[6]. The Celebes pygmy stegodont M_3 is decidedly smaller than its counterpart in *Stegodon trigonocephalus* from Java, but has not developed the high molar crowns: its height–width index is only 67 (Table 1).

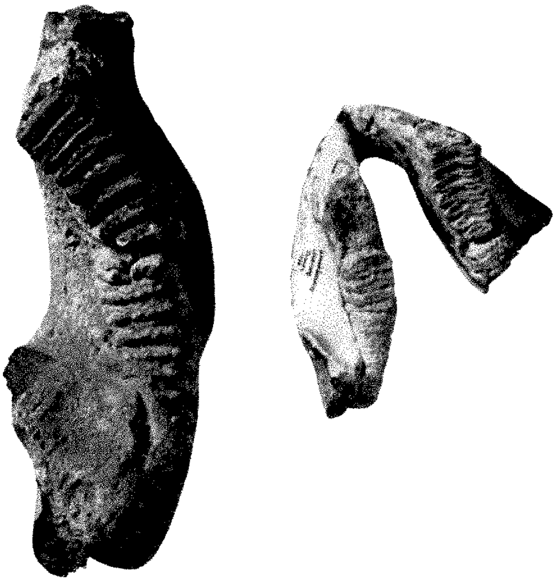
Finally, two forms of *Stegodon* have been recorded from Timor[7], one only half the linear dimensions of *Stegodon trigonocephalus* from Java but with a very high molar crown, *Stegodon timorensis* Sartono, and the other hardly smaller than the Java *Stegodon trigonocephalus* and apparently indistinguishable from the Flores race of this species. The smaller of the two Flores forms and the larger of the two Timor forms are based only on a few worn milk molars (Table 2 and Figs. 2 and 3).

Table 2. MEASUREMENTS OF MILK MOLARS OF VARIOUS SPECIES OF *Stegodon*

		S. trigonocephalus florensis		*S. timorensis*	
	Java	Flores	Timor	Flores	Timor
DM^3, length	51–58	—	44	—	—
width	34–45	—	32	—	—
DM_3, length	56–68	—	—	28	—
width (anterior)	23–28	20	—	14	—

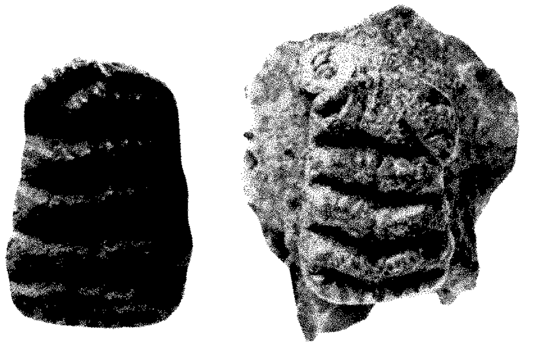
Measurements are in mm.

It seems likely that the two Flores stegodonts will prove to be identical with the two Timor forms. This, then, would make for an interesting palaeozoogeographic conclusion: the islands of Flores and Timor may not have been sufficiently isolated from each other in the Pleistocene to prevent the dwarfing *Stegodon* populations from wandering back and forth. Otherwise, it is hard to see how the two evolutionary products on Flores and Timor could have been so similar. Celebes remained well isolated from these Lesser Sunda Islands, by a strait at least 50 miles wide even during Pleistocene low sea-level stages, and its *Stegodon* is very distinct: it did not develop high molar crowns.



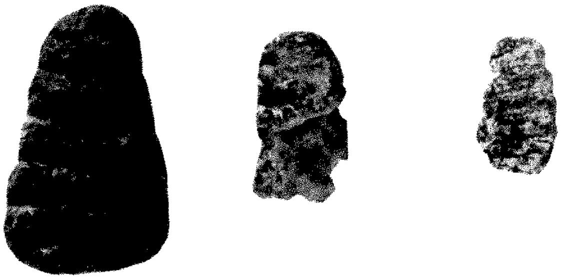
Java Timor

Fig. 1. Half-mandible of *Stegodon trigonocephalus* Martin from Java (left) compared with mandible of *Stegodon timorensis* Sartono from Timor (right). The left last molar is 24 cm long in the Java against 12 cm in the Timor specimen. (Both figures × 3/16.)



Java Timor

Fig. 2. Right DM^3 of *Stegodon trigonocephalus* Martin from Java (left) compared with left DM^3 of *Stegodon* cf. *trigonocephalus florensis* Hooijer from Timor (right). (Both figures × 2/3.)



Java Flores Flores

Fig. 3. Right DM_3 of *Stegodon trigonocephalus* Martin from Java (left) compared with anterior portion of left DM_3 of *Stegodon trigonocephalus florensis* Hooijer from Flores (centre) and with left DM_3 of *Stegodon* cf. *timorensis* Sartono from Flores (right). (All figures × 5/8.)

The route of dispersal of the stegodonts from Flores and Timor was evidently along the Lesser Sunda Islands chain from Java; various recent Asiatic mammals have spread along this chain to Timor. It is only remarkable that among the extinct forms *Stegodon* alone should have reached Flores and Timor; no fossil remains of other mammals (apart from a jaw of a small murid rodent, *Papagomys*, in Flores) have been found along with the *Stegodon* fossils. The ancestral form of the Celebes *Stegodon sompoensis* may have migrated from the Asiatic mainland via Formosa and the Philippines.

The geology of the *Stegodon* sites in Celebes, Flores and Timor is largely unknown. It is possible that *Stegodon timorensis* is of more recent origin than *Stegodon trigonocephalus florensis*. If so, the former could have descended from the latter; the trends toward smaller size and higher molar crowns that distinguish *Stegodon trigonocephalus florensis* from its parent species of Java are merely carried on further in the Timor species. On the other hand, the two forms may prove to be contemporaneous; from the ratio in linear dimensions of teeth and bones, five to three, it follows that *Stegodon trigonocephalus florensis* had five times the body size of *Stegodon timorensis*, a difference probably large enough to permit coexistence.

Chlorotic Dwarf of Eastern White Pine caused by an Ozone and Sulphur Dioxide Interaction

CHLOROTIC dwarf disease of eastern white pine (*Pinus strobus* L.) is a physiogenic condition characterized by stunted roots and tops, mottled needles and premature foliar abscission. Recent work has indicated that the disease is caused by gaseous pollutants that injure the needles of genetically susceptible white pines[1]. We have now shown that the action and interaction of ozone and sulphur dioxide cause characteristic symptoms on the foliage of white pine ramets that are susceptible to chlorotic dwarf.

Between June and September 1967, we took continuous measurements of ozone and samples of sulphur dioxide every 2 h from Monday to Friday. We worked in Ohio white pine plantations where there was a high incidence of chlorotic dwarf, aiming to assess the possible role of these toxicants in the induction of the disease. A Mast ozone meter, equipped with a chromium trioxide scrubber[2] to eliminate interference from sulphur dioxide, monitored concentrations of oxidant (ozone). Readings were corrected by a factor of 1·5 to give oxidant values in terms of neutral KI. Sulphur dioxide was collected with a sequential sampler, and concentrations were determined by the method of West and Gaeke[3].

Daily 2 h peak concentrations of sulphur dioxide varied from 0·0 to 7·8 p.p.h.m. Two hour averages of 5·0 p.p.h.m. of sulphur dioxide were recorded on 25 per cent of days. Maximum hourly averages for oxidant (ozone) registered greater than 5·5 p.p.h.m. for 60 per cent of days. The greatest hourly average was 21 p.p.h.m., and concentrations larger than 10 p.p.h.m. were common. The greatest combination was 12 p.p.h.m. of oxidant and 7·8 p.p.h.m. of sulphur dioxide. Concentrations of sulphur dioxide and oxidant in the field were both greater than 5 p.p.h.m. on 16 per cent of days. Measurements made throughout the summer of 1968 were similar.

Table 1. MOTTLING ON WHITE PINE AFTER EXPOSURE TO 10 P.P.H.M. OF SULPHUR DIOXIDE AND/OR 10 P.P.H.M. OF OZONE

Treatment	Concentration p.p.h.m.	Replications No.	Injury* per cent
Ozone	9·9		
Sensitive		9	3
Resistant		2	0
Sulphur dioxide	9·6		
Sensitive		6	4
Resistant		3	0
Ozone/sulphur dioxide	9·9/9·8		
Sensitive		9	16
Resistant		3	0
Control	0		
Sensitive		6	0
Resistant		5	0

* Injury was rated on the percentage area of needles showing the chlorotic mottling condition.

In our experiments with ozone and sulphur dioxide we fumigated some resistant and sensitive clonal material of white pine that had been grafted onto 2 yr rootstocks in 1964. White pine plants were placed in a cold storage room in the autumn of 1967, and groups were removed at intervals after 8 weeks. Dormancy was broken in a growth chamber in a regime of 16 h day, 2,000 foot candles of light, 26° C daytime temperature, 21° C night temperature and 60–74 per cent humidity. After the buds had broken and the candles had begun to elongate, but before the needles separated within the fascicles, the plants were placed in charcoal-filtered chambers[4].

Sensitive and resistant white pine ramets were exposed to 10 p.p.h.m. of sulphur dioxide, or to 10 p.p.h.m. of ozone, or to mixtures of the two (each in a concentration of 10 p.p.h.m.). Control plants remained in the charcoal-filter growth chambers. Other white pines were fumigated for 4–8 h each day, 5 days a week, for 4–8 weeks between January and April 1968 (Table 1).

Symptoms were not observed on any resistant ramets or sensitive controls. Chlorotic dwarf symptoms of flecking (mottling of current needles), occasionally accompanied by a shedding of older needles, were noted on most sensitive pines. There was little or no injury to plants treated with one of the gases, and moderate injury in those treated with the gaseous mixture. The percentage of mottling on current needles and the premature drop of older needles exposed to the mixture far exceeded the damage in those treated with one gas. This strongly suggests that the two pollutants act synergistically on sensitive white pine plants. A similar response has been reported in tobacco[5].

For a brief time during growth, needles were extremely susceptible to damage by pollution. Chlorotic mottling developed 2–4 weeks after exposure began (about the time that the needles separated in the fascicles). Subsequent exposure intensified the mottling only slightly.

We have found that ozone and sulphur dioxide, acting independently or synergistically, can promote the initial symptoms of current needle mottling and premature defoliation associated with the chlorotic dwarf syndrome. Sulphur dioxide seems to be much more reactive than ozone in producing the symptoms.

With continued breakdown of chlorophyll and loss of leaves, as observed in these long term exposures, growth could be reduced through the inability of the leaves to supply the normal photosynthetic needs of white pine plantations[6].

Other white pine needle blights that seem to be related to air pollution may be caused by a mixture of two or more pollutants. When recorded levels of single gases are not great enough to damage white pine, mixtures of gases may injure trees before either pollutant would itself cause any damage.

Environmental factors also directly influence the sensitivity of white pine to one or more pollutant. Further study of these interactions between the suscept and its environment should help to explain variations in the expression of symptoms.

ORDERED ELEMENTS

The Periodic System of Chemical Elements

A History of the First Hundred Years. By J. W. van Spronsen. Pp. xv + 368. (Elsevier: Amsterdam, London and New York, 1969.) 120*s*.

THE importance of the periodic system in modern thought has never been adequately estimated or expounded. More than any other interpretation of physical nature except Newton's, it made clear the orderliness and potential comprehensibility of the material world. One reason why nobody has yet written an appreciation of its effect on the rest of science, let alone on modern philosophy, religion or literature, is that its history has been taken too much for granted. Chapters on it included in general histories of chemistry have usually repeated a few names and a few incidents, but have, by and large, neglected critical appraisal of its deeper consequences.

Now, van Spronsen has made an important and substantial contribution to the history of chemistry. The "Hundred Years" of his title is not to be taken literally: after a survey of the relevant features of the earlier history of chemistry, he begins his detailed study with the precursors of the modern classification system (for example, Döbereiner 1817) and goes on eventually to discuss the significance to classification of the quantum theory and the trans-uranium elements, covering more than a century and a half. In the period from Döbereiner's second essay (the triads of 1827) until Mendeléev's own second main paper of 1871, van Spronsen excels all previous writers on this subject in the completeness of his account. He shows how the Mendeléev system was the culmination of an irregular development, confidence among chemists that there was a system to be elucidated growing stronger decade by decade after 1827.

He draws attention to many important chemists whose work on classification has been forgotten, Dumas in particular. It is striking to see how the search for a grand design was frustrated again and again, paradoxically by a concentration on quantitative factors. As atomic weight determinations grew more precise and reliable, the arithmetic of the relation between their numerical values was pursued with such energy as to obscure the significance of mere sequence. One reason for this is that molecular weight determinations were also becoming more precise, so that the homologous series of organic compounds presented a very persuasive, but misleading, model for a theory of atomic weight relations. One incident in the long history of scientists failing to communicate is the proposal by Beguyer de Chancourtois of a helical distribution of atomic weights. He showed a periodicity but did so without clarity or force. He was well on the right track but his ideas were not published diagrammatically in a clear enough way. Van Spronsen does him justice as he does also to a virtually forgotten chemist, the Dane Hinrichs, who emigrated to become a good American and a good teacher. Hinrichs' flat spiral shows enough periodicity to be worth more than a mention.

The better known men, Odling, Newlands and Lothar Meyer, are fully dealt with, but this does not diminish the standing of Mendeléev. He sought a means of putting order into his teaching and in doing so produced not only a new foundation for the whole of chemical teaching, but also a unified theory and a stimulus to research, a very great achievement.

Van Spronsen examines the various predictions of new elements, the gradual solution of problems like the deviation from weight order, the assimilation to the system of the noble gases, and the inevitable debates on priority. He brings the story up to the point where it can be seen to be continuous with recent progress in physics and chemistry. Every section is well illustrated with original or adapted diagrams and tables.

This book can hardly fail to have a beneficial effect on the study not only of the periodic system but of chemistry as a whole. Perhaps it may even encourage somebody to attempt a general appreciation of the place of the periodic system in modern thought. FRANK GREENAWAY

PHENOMENOLOGICAL CLASSIC

Formal and Transcendental Logic

By Edmund Husserl. Translated by Dorion Cairns. Pp. xix + 340. (Nijhoff: The Hague, August 1969.) 30.60 guilders.

EDMUND HUSSERL began his life as a mathematician, but as a philosopher he moved steadily away from rigorous deductive procedures into a preoccupation with problems of the psychology of perception. Thus his intellectual development diverged widely from that of Bertrand Russell, and this divergence expressed the great cleavage which has developed during this century between continental European schools of philosophy and those of the English-speaking world. The same cleavage is reflected in the fact that 40 years elapsed between the original publication of this major work of a leading European philosopher and its first English translation, a labour of devotion by Professor Cairns.

Formal and Transcendental Logic is a very abstract and technical work which uses a somewhat esoteric vocabulary. Serious philosophers with an interest in phenomenology will welcome it and study it, but it is hardly a work which will be suited to the needs of the average scientist in search of a philosophical basis for his thinking. Husserl himself was interested in science, and he hoped that his phenomenology would provide a better basis for scientific thinking than other modern philosophies could. Oddly enough, the author of *Cartesian Meditations* tends to turn to Euclidean geometry when he wants an example of scientific method.

Formal logic is the kind that is classically formulated in Aristotle's *Analytics*, and the first part of Husserl's book is devoted to an examination of its nature and limitations, when looked at from the point of view of the psychology of perception. "Transcendental", in Husserl as in Kant and Hegel, means concerned with the intrinsic nature of existing things, rather than with mere perceptions or concepts; the Hegelian dialectic was proposed as a procedure of transcendental logic, though Husserl does not deal with it in this book. The latter half of it is an attempt to explain how transcendental logic differs from and transcends the formal variety, without invalidating or negating it. The book does not include, nor did Husserl ever formulate, a direct exposition of the principles of transcendental logic on the lines of the *Analytics*.

For scientists, without the philosophical training required by a reader of this book, there are two currently available works which provide in more readily understood form critiques of formal logic basically similar to that of Husserl and which both look forward to something like the transcendental logic which he advocated; they are Michael Polanyi's *Personal Knowledge* and Stephen Toulmin's *The Uses of Argument*. Those who have read and understood works like these might be ready to begin the study of Husserl's philosophy. R. A. CROWSON

THEORY OF BONDING

Elementary Molecular Bonding Theory

By Peter G. Perkins. (Methuen's Monographs on Chemical Subjects.) Pp. viii + 183. (Methuen: London, October 1969.) 28*s*.

Chemists of all types and sizes have always been interested in theories of bonding. In recent years, theoretical chemistry has advanced to a point where it is possible to claim that we understand the principles of atomic interaction. Current work is devoted to investigating quantitative aspects of the theory applied to particular molecules, and—all too rarely—to predicting new molecular structures and properties. The established approach is through molecular orbitals, which represent many-electron structures in terms of one-electron functions; electron correlation can be incorporated through "configuration interaction".

The aim of this little book is to present the modern theory of the chemical bond at an elementary level suitable for sixth-form pupils and for students at universities and technical colleges. This is a worthy but challenging objective. To reach it, an author needs to be the complete master of his subject and to possess that rare gift of clear exposition.

This book begins with a discussion of early ideas of bonding and then introduces Schrödinger's equation and atomic orbitals. The third chapter is on valence bond theory, which could well have been omitted. The fourth chapter is on molecular orbitals in diatomic molecules, and the fifth on molecular symmetry and orbitals in polyatomics. Finally, there is a short summing-up.

There are a number of obscurities and inaccuracies that mar the book. On page zero e is given with the wrong sign. Many of the figures are poor (Fig. 2.18 should be inverted, plane I in Fig. 5.6 fails to look anything like a mirror plane, and Fig. 3.15 is not easy to follow), and some have left-handed coordinate frames. Also, Mulliken's recommendation for the choice of axes to describe a molecule like H_2O (the two-fold rotation axis should be z, with x perpendicular to the molecular plane) has not been adopted. Nevertheless, the author has a pleasing style and his book is bound to be useful to critical students. It may not, however, possess the clarity required of a book that is to make an important contribution to sixth-form teaching. A. D. Buckingham

REFINING PROCESS

Electro-Slag Refining

By W. E. Duckworth and G. Hoyle. Pp. x + 178 + 44 plates. (Chapman and Hall: London, November 1969.) 80*s*.

The technology of steel manufacture has developed rapidly in recent years to meet the increasingly more stringent requirements for closer tolerance on composition and freedom from non-metallic inclusions. During the past decade, electro-slag refining (ESR) has progressed from the status of a laboratory technique to a manufacturing process for the production of high-grade steels, comparable in output to vacuum arc remelting (VAR).

The process was first exploited in the Soviet Union, but is now in use in many countries. In Great Britain, a development unit was set up, under the leadership of the two authors, by the British Iron and Steel Research Association, and this has now acquired an international reputation in electro-slag technology. The book gives a detailed and fascinating account of the evolution of the process to the present stage of development. A treatise, published in Russia in 1963, referred only to work carried out in the Soviet Union. This is the first book to appear in the English language and the authors have attempted to collect an accurate account of the process in all the countries in which it is being applied.

The first half of the book describes the fundamental principles of the process and reviews present knowledge of the physical and chemical properties of the various slag compositions which have been studied. The conditions controlling the gas–slag–metal reactions are described and data are presented to aid in the selection of the optimum operating conditions for specific purposes. The research worker may regret the absence of consideration of the mechanisms of inclusion removal, but the authors have concentrated on established facts and have avoided the areas which are still controversial.

The second half contains descriptions of typical plant installations and operating techniques. Twenty-one tables list changes in composition and mechanical properties resulting from electro-slag refining of various grades of steel. The economics of the process are honestly examined and it is shown that present costs of ESR are comparable with those for VAR.

The authors state that they have tried to "present a rounded account of the state of knowledge" of ESR and "make it more widely known than is the case at present". They have succeeded in the first objective and anybody who reads the book cannot fail to be impressed by the potential of the process.

The book is well written, illustrated and presented. A minor criticism is the frequent reiteration of statements on successive pages in chapter three. C. Bodsworth

CONTROLLED NUCLEAR FUSION

Plasma Physics and Controlled Nuclear Fusion Research

Vols. 1 and 2. (Proceedings of the Third International Conference on Plasma Physics and Controlled Nuclear Fusion Research held by the International Atomic Energy Agency at Novosibirsk, August 1–7, 1968.) Vol. 1: Pp. 998. Vol. 2: Pp. 836. (International Atomic Energy Agency: Vienna; HMSO: London, 1969.) Vol. 1: 191*s* 8*d* ($23); Vol. 2: 162*s* 6*d* ($10.50).

The 1968 conference at Novosibirsk may well be remembered as the conference where the ghost of Bohm diffusion was laid. Experimental evidence reported at the conference showed that containment times of 50 to 100 Bohm diffusion times could now be achieved in laboratory plasma. The quest for a thermonuclear reactor is on the up again.

The two volumes contain a total of 134 papers of which 80 are in English, 37 in Russian and 10 in French. The Russian and French papers have an English abstract. Translations of the Russian papers have already been published in *Nuclear Fusion*. It is a great pity, for Western readers at least, that the Russian and French papers could not have been translated before publication, more so because these volumes should remain a standard reference for a few years to come.

The first paper in the book is an extremely useful, but unfortunately rather short, review by Artsmovich of the present position in closed confinement systems. In another review, Buchsbaum argues for the continuation of study of mirror machines because of the relative ease of experimentation. This view is to some extent reflected by the number of papers presented at the conference on open ended machines. A feature common to most of the theoretical papers is that an effort is now being made to apply various theories to realistic geometries. Some of the experimental contributions already show that such a trend is most fruitful and will be even more so in the future.

These two volumes are obviously going to be standard reference books for those interested in controlled nuclear fusion. They also contain a large amount of information, particularly on the theoretical side, which will be of use to those engaged in more general studies of the plasma state. As is usual for IAEA publications, the printing and general layout are excellent. George Rowlands

NUCLEAR FUSION INTRODUCED

Nuclear Fusion

By H. R. Hulme and A. McB. Collieu. (The Wykeham Science Series for Schools and Universities.) Pp. vii + 153. (Wykeham: London and Winchester, 1969.) 20*s*.

THE "Wykeham Science Series" is intended to broaden the outlook of senior grammar school pupils and to introduce undergraduates to the present state of science, but it is difficult to see how *Nuclear Fusion* can be recommended to grammar school pupils or even to first-year undergraduates. The introduction is confused and its level is such that real understanding is likely to be achieved only by a young reader with a wide range of background knowledge or exceptional ability. The book might perhaps be useful in a school or undergraduate library as a reference book if it were not for the total lack of references or any guide to further reading.

The mature reader with a good knowledge of physics may, however, find considerable enjoyment in the later part of the book, which deals in some detail with thermonuclear reactions in the laboratory, the problems of plasma physics, and the technological and engineering problems associated with fusion reactors. For such a reader, an attractive feature of the book is the wide range of peripheral topics which are covered. These include the evolution and abundance of the elements, cosmological theory, neutrinos and superconductivity.

DAPHNE F. JACKSON

ATMOSPHERIC MOTION

Atmospheric Circulation Systems

Their Structure and Physical Interpretation. By E. Palmén and C. W. Newton. (International Geophysics Series, Vol. 13.) Pp. xvii + 603. (Academic Press: New York and London, July 1969.) 243*s*.

IN meteorology, as probably in most other rapidly advancing sciences, ideas need to be continually revised. There is so much new information that it deters even perfunctory review, while the work of digesting, clarifying and relating the gains over the whole field, for the benefit of philosophers and recruits, is perhaps passing beyond the powers and devotion of individuals. Consequently there is a dearth of good texts, and every new book published is inspected hopefully.

This book, by two authors whose contributions to the analysis of large-scale atmospheric phenomena are everywhere known and respected, has a disarming preface. "It is possible," they say, "that some readers will consider this book somewhat too qualitative or descriptive and perhaps not up to date in every respect." Well, yes, I am one of those readers, but I am grateful for the book for all that, and I commend it to others.

The atmospheric circulations which are discussed are those in the troposphere and of large scale; although attention is paid to the intense cumulonimbus, ordinary cumulus convection is represented only by transfer coefficients, and circulations of intermediate scale, such as those associated with sea breezes, are not considered. The authors choose to begin on the scale which is global, and then to reduce it, though not quite steadily. The chapters deal successively with the mean annual general circulation; its seasonal variation; air masses, fronts, jet streams and tropopauses; the polar front theory; "upper waves"; extratropical disturbances; fronts and jet streams (in more detail) and frontogenesis; three-dimensional motion in and the development of extratropical disturbances; their weather; cumulonimbus; tropical general circulation and disturbances, including hurricanes; and finally a review of the energetics of the various circulations.

The interposition of the discussion on fronts between those on the general circulation and the extratropical disturbances is symptomatic of a peculiar adherence to the so-called polar front "theory" (better regarded and respected as a philosophy and technique of analysis). The polar front had to be replaced by the broad baroclinic zone before a satisfactory theory of cyclones was evolved, and it is rather startling now to read of "the special importance of the polar-front theory for our present knowledge" (page vii), to find the name of Eady mentioned only once (separately from a single page given to the perturbation theory of cyclogenesis), and to read of the "general rule" that "the physical cause for the deepening of cyclones must be ultimately sought in an examination of the higher levels" (page 134). For a while, the impression grows that a cyclone is a pressure minimum on the surface weather map, although eventually (page 542) it seems "proper to consider a cyclone in the broad sense as including the neighbouring anticyclonic regions", and previously (page 338) it has been emphasized that a front is, "at least in some cases, a characteristic acquired by a cyclone during, rather than prior to, its development". Such old-fashioned attitudes are, however, usually later offset by references to recent studies, and do not affect the discussion of mean circulations and tropical disturbances.

Although the title of the book refers to physical interpretations, the relinquishment of the insight provided by perturbation theory and numerical solution of the equations of motion constrains it to detailed description without satisfactory understanding. Insistent compilation of fairly well balanced budgets of various properties, which certainly injects a backbone of quantitative and very interesting discussion into the book, is consistent with the view expressed on page 2 that the mean circulation and the disturbances "co-operate in a physically harmonious fashion to balance the energy and momentum budgets", but does not provide physical interpretation as I regard it.

Nevertheless, it would be absurd to complain that the book does not contain all one would like. It represents a great and valuable labour by the authors. It has more than 200 diagrams, of the kind one is glad to have collected together (although some suffer from the small page size), and several hundred references, work from practically all of which is sensibly incorporated into the text. It will stand as the most complete description of large-scale phenomena presented before the era of numerical analysis, satellite survey, and collaborative observational studies brought the need of surveys even more comprehensive, yet unified by physical reasoning. We will have to wait a long time before any appear, and in the meantime we can be well pleased to have the book which the authors have given us now.

F. H. LUDLAM

ALKALOID STRUCTURES

The Chemistry of the Isoquinoline Alkaloids

By Tetsuji Kametani. Pp. 265. (Hirokawa: Tokyo; Elsevier: Amsterdam, London and New York, 1969.) 145*s*.

THIS book is a compilation of data and references on isoquinoline alkaloids. All of the obviously isoquinoline structural types are included as well as those, like the colchicine and Amaryllidaceae alkaloids, which are related biosynthetically. The book thoroughly covers the literature to the end of 1967.

The tables of data are preceded by a short descriptive introduction to the field which in twenty-two pages can do no more than sketch in a very small sample of typical structural, synthetic and biosynthetic work on isoquinoline alkaloids. It is too brief to be of much value either to workers directly involved in the field or to the general reader, but would serve as a useful starting point for those newly entering on a study of this group of alkaloids.

The principal part of the book is divided into twenty-three sections, each dealing with a particular structural type. All the known alkaloids falling into the structural family are listed in order of increasing molecular weight. For each compound, the structural formula, melting point, specific rotation and plant sources are given; references to the original literature are provided for spectroscopic data and separately to relevant structural, synthetic and biosynthetic investigations.

The lay-out is good in general and the book is easy to use, though there is a unique system of abbreviations (for example, Ph = Physical data). Most of the structural formulae are rather inelegant and old fashioned in appearance, but they are rarely ambiguous. Curiously, occasional formulae are far clearer and modern in appearance (*cf.* adlumidine *versus* bicuculline on page 136).

This book, which has been compiled by a leading figure in isoquinoline alkaloid chemistry, will prove as useful a reference work to those engaged in this field as Hesse's *Indole Alkaloids* does to those studying this other large group of alkaloids. Unfortunately, as a result of the long time involved in its publication and the volume of work in this field in the past two years, the lists are already considerably out of date. It is to be hoped that Professor Kametani will, in due course, be able to produce further editions to update this one. A more rapidly published further volume would better suit the objectives of a book of this kind, particularly if the cost could also be reduced. J. A. JOULE

GENETICS FOR DOCTORS

An ABC of Medical Genetics

By C. O. Carter. (Reprinted from *The Lancet*, May 17 to June 28, 1969, with two additional chapters.) Pp. 94. (The Lancet: London, November 1969.) 15*s*.

THE title of this excellent little monograph could deceive if it is overlooked that it was first published in *The Lancet*. It is clearly intended primarily for doctors or medical research workers who want a guide to medical genetics which is short, clear and inexpensive but not entirely elementary; knowledge of Mendelian genetics and medical terminology is assumed. Bearing this in mind, the book fulfils its purpose admirably. The original chapters cover chromosome mutations, mutant genes of large effect, polygenic inheritance and common diseases, and genetic counselling. One additional chapter consists of "a formidable list of the most common single-gene-determined disorders which the paediatrician is likely to meet"; this is something not hitherto readily available cheaply, and which would alone justify purchase of this book (high marks to any doctor who can characterize a majority of the listed disorders; the overconfident might start on Stargardt's disease, Weill–Marchesani syndrome or leprechaunism).

The author writes with easy authority; depth is not sacrificed to brevity, and chapter references provide an excellent and up to date compendium of basic reading. There are one or two surprising omissions; for example, there is no mention of the Lyon hypothesis of random X-chromosome inactivation, although it is tacitly taken for granted. And there is no consideration of pharmacogenetics, which might be more relevant for practitioners than the theory of gene action (now adequately dealt with in most genetic textbooks). The book is, however, by contrast, particularly strong on the author's own interests, such as twin and familial studies and their bearing on polygenic inheritance.

The last chapter, on the control of genetically determined diseases, brings home the need for a large scale study of amniocentesis; now that this is clearly of value for the detection *in utero* both of chromosome abnormalities and of homozygosity for certain deleterious recessive conditions, the time seems to have come for a full assessment of the risks involved, and of its feasibility as a regular diagnostic technique for eugenicists.

E. H. R. FORD

REVERED EMBRYOLOGIST

Organization and Development of the Embryo

By Ross Granville Harrison. Edited by Sally Wilens. Pp. xxiv + 290. (Yale University Press: New Haven and London, November 1969.) 135*s*; $15.

ROSS HARRISON'S contributions to experimental morphology were of outstanding importance, but were offered with a diffident and, in some cases, almost a casual air. He is most widely remembered for having "invented" tissue culture in order to solve a simple, but cardinal, problem in neurogenesis. In fact, of course, he was not the inventor but the first to succeed in establishing a technique good enough to allow morphogenetic questions to be tackled *in vitro*. The method and the results were published in two preliminary papers and the whole story was only told a few years later, and with a minimum of fuss. His later work on limb polarity and on growth control was of equal intellectual importance, but its presentation was almost perversely modest. Nobody could have done more to invite under-estimation by posterity.

In 1949, towards the end of his working life, Harrison delivered the Silliman lectures but, perhaps predictably, deferred too long their writing up for publication. The present book is a posthumous substitute. It includes several of his earlier review papers (from the 1930s) on subjects cognate to the matter of the lectures. These are interspersed with, and interrupted by, additional material taken from his notes for the lectures and the pictures used to illustrate them. The result is a very handsomely produced memorial volume which contains the essence of his mature views on the major problems of animal development. One's only complaint is that the method of introducing the later material into the text is often confusing. Straight reprints of the papers with appendices would have been better.

The five principal chapters cover problems of cellular differentiation, the significance of tissue culture, neurogenesis, symmetry relations and the uses of heteroplastic grafting. A sixth chapter publishes, at last under his own name, the celebrated Harrison normal staging of *Ambystoma punctatum* which has been widely quoted in print for more than twenty years by other workers. The book ends with a brief summary chapter followed by a list of Harrison's publications.

Although this book will most please the older experimental embryologists for whom Harrison was, and rightly, a revered figure, it would be quite wrong to think that it has no present-day relevance. Most of the problems which the ingenuity of Harrison and his contemporaries exposed and clarified are with us still. D. R. NEWTH

MOVEMENTS IN PLANTS

Physiology of Plant Growth and Development

Edited by M. B. Wilkins. Pp. xxi + 695. (McGraw-Hill: Maidenhead, 1969.) 126*s*.

THIS volume describes itself as a textbook of whole plant physiology specifically aimed at advanced undergraduate and postgraduate students. Eighteen topics have been selected and appropriate authorities give a summary of the present state of thinking in these fields, as well as a background of the major experimentation that has led to the present views.

The first three chapters are devoted to a survey of auxins, gibberellins and kinins, giving the historical events leading to their discovery and isolation, together with the major effects of each of these types of hormones on different growing systems. The bias, as the title of the book implies, is towards physiological responses rather than to the biochemical implications of hormone regulation. The fourth chapter describes the phenomenon of polar transport in plant cells, and although there is little discussion or speculation on the mechanism by which molecules of hormones or other growth substances are moved through cells more easily in the downward than the upward direction, the author provides a comprehensive review of the facts as they are at present known.

There follows an exciting chapter on apical dominance in which the reader is led through the different theories which might account for suppression of lateral bud growth. The experiments are well described and the discussion ends with a set of clear summaries. The chapters on geotropism and phototropism follow in the same vein, and both define the major problems that still need clarification. Nastic responses are covered in an excellent chapter with a special emphasis on the rapid and so far unexplained movements of the sensitive plant *Mimosa pudica*.

A discussion of the factors governing the movement of stomata leads on to a clear chapter on photosynthetic processes and to another which sets out the problems and the theories of how carbohydrates synthesized in the leaves are translocated from one part of the plant to another. The evidence for long distance transport of metabolites within the highly specialized cells of the phloem is then summarized. The problem of how water is taken up and moved in a plant is described from a thermodynamic viewpoint. The pathway followed from root to leaf receives very adequate treatment, and an associated chapter deals with the mechanisms by which ions are taken up from aqueous solutions, and discusses how they too can be moved from one part of the plant to another.

The discovery and properties of the photosensitive pigment phytochrome are attractively told by one of the collaborators in this work. It precedes a comprehensive account of the part now seen for phytochrome in the regulation of plant morphogenesis in response to specific quanta and wavelengths of light. A discussion of photoperiodism and vernalization follows, in which the reader is acquainted with the effects of other environmental factors, day length and low temperatures, on the development and differentiation of plants. In a subsequent chapter the author discusses the problems of how and why and to what signals plants respond when they stop active growth and enter into the latent stage of dormancy, and what factors initiate the resumption of growth, as in the germination of a seed.

But the pattern of plant growth is not confined to a direct response to changes in the environment, for plants also measure time. In a final chapter on circadian rhythms the problem of why once a response to the environment is set in motion, it can be repeated at near 24 hour intervals under uniform conditions, serves as a good introduction to the study of biological clocks.

The errors in this volume are few, the references are comprehensive and are generally well chosen and the presentation is clear. Each chapter states the problems and the major facts and theories and seldom falls into the trap of supplying an unquestioned solution. The reader is left with ideas of how future research may develop and some of the experimental difficulties to be encountered. Most of all, this book encourages thought and achieves what it has set out to be—a very useful textbook for both undergraduates and postgraduates.

DAPHNE J. OSBORNE

COMMUNICATION UNDISPUTED

Communication

A Discussion at the Nobel Conference. (Organized by Gustavus Adolphus College, St Peter, Minnesota, 1969.) Edited by John D. Roslansky. Pp. ix + 131. (North-Holland: Amsterdam and London, 1969.) 42*s*.

ONCE again a group of people from widely diverse fields have been brought together to state their positions in terms which are clear to laymen and students alike. Communication is interpreted in the widest possible sense and the result is hardly the "discussion" that the subtitle claims. If you get people as diverse as these, and ask them to speak simply, they inevitably deal largely in generalizations making everything seem black or white. This is not to say that the participants did not say things which were interesting and often important. Augenstein considers the implications of our ability to change the "little black box called the mind"; whose ideals shall be inculcated ? To judge from this chapter, there must have been some splendid audience participation during the paper. The dangers of over-simplification are vividly demonstrated by the argument that Caryl Cheesman's beliefs enshrined in his memory were all that caused him to rape and murder; *ergo* change his memories and your criminal is reformed. Marler is on happier ground with his review of communication in the animal kingdom, pointing out clearly how all the design features of a language, proposed by Hockett and Altmann, can be exemplified somewhere in the animal kingdom, but appear together only in human language. Chomsky would find the essentially human character of man's language in its creativity which, he believes, reflects inherent properties of the human mind. Kaplan, speaking as a philosopher, underlines the importance of communion as distinct from communication; all too easily humans may communicate without communion.

But it is Lenneberg's contribution—as a psychologist—in which there appears the only real sign of the inter-disciplinary sparring which should be the real purpose of such gatherings. He criticizes the experiments by the Gardners on chimpanzees in which they taught the animals sign "language"; unlike Marler, he believes that the existence of this language is not proved, and he describes the critical experiments which he would like to see performed in order to settle the question.

There is therefore little real discussion and little comparison of the viewpoints of linguistics, philosophy, animal behaviour, psychology and so forth. Nevertheless, the papers make good reading as brief reviews of their authors' viewpoints.

Correspondence

NERC Support for University Research

SIR,—Your issue of December 6 last contained two constructive articles about my council's activities and policy arising from the publication of our annual report for 1968/69. Each raised, however, certain misgivings about the support by the council of research at universities. I would be grateful to have a little of your space to explain the position, and perhaps in so doing to assist your readers to distinguish between fact and hearsay in the article "Goldfinger no longer" of your issue of January 3, 1970.

There are perhaps three main points made in this series of articles concerning our policy for support of research in universities that deserve an answer. The first is that on the face of it NERC loaded itself with too many commitments when it was being encouraged to expand. I think the trouble here is partly due to a misunderstanding about our funding of university research arising from the difference between the total value of new grants awarded in a given year and the total expenditure on all grants, new or existing, in that year. The former figure is not expenditure but new commitments extending for several years ahead, depending on the duration of the grants. In steady conditions the figures for both new awards and annual expenditure will move together, but in practice these conditions have never arisen.

	1966/67	1967/68	1968/69	Estimated 1969/70
Total value of new awards (academic year, October–September)	1·8	1·2	0·9	(1·0)
Annual expenditure (financial year, April to March)	0·69	0·89	0·93	(1·2)

In particular, at the end of the last university quinquennium in 1967, a large proportion of existing grants terminated. It was necessary in that year, in order to sustain a steady growth in subsequent annual expenditure, to enter into an exceptionally large commitment on new awards, although this level of new commitment could not, and was never intended to be, sustained. The effect of the transition from one quinquennium to the next can be seen by comparing figures for value of new awards with those for annual expenditure on research grants, both given in millions of pounds.

These figures show that our annual expenditure on university research grants is likely to increase by about 75 per cent over the past 4 years from 1966 to the present time.

The second point concerns the fact that only 15 per cent of NERC's expenditure as shown in our financial statement for last year went to universities. These figures for university support are not, however, comparable as they stand with expenditure on research elsewhere by the council. In particular they exclude capital expenditure on buildings, equipment that is a regular part of the facilities of the department concerned, and supporting costs and services, all of which are provided at universities by the UGC but in our own institutes have to be included in the NERC expenditure. In the marine field the major part of the activities of our Research Vessel Unit, of the RRS John Murray and of the use of marine research equipment held at the Research Vessel Unit, are devoted to the needs of universities. Thus both in actual money and in research effort, our effective support of university research is a substantially larger fraction of our total expenditure than appears from the figures shown in the financial statement under that head for accounting purposes.

Our general policy towards support of university research in the environmental sciences has been dealt with at length in our current annual report. I need only say that we believe our support must be selective, should be guided (but not inhibited) by broad strategic objectives, and ought to link up with the programmes of our institutes whenever it is sensible and productive to do so. This brings me to the third point, namely, the use of the so-called "success rate", that is, the ratio of funds awarded to funds applied for (which last year was just over one-third overall), as a measure of this disappointment.

In fact, this ratio as it stands is a very unreliable index of the true extent to which our support is falling short of the total legitimate and deserving requests. Some of the applications we receive, including the largest ones, are either outside our remit or are for other reasons unsuitable for support. We believe it is right to bring all of them to the attention of one or other of our grant-awarding committees rather than to make the situation look more rosy by pruning them beforehand. Sometimes it is possible to find ways of achieving the desired research objectives more economically, particularly by sharing expensive equipment between universities or with council establishments. In some cases an award is made initially for a shorter period than is requested, with the possibility of an extension if promising results are achieved. Our grant-awarding committees would be failing in their task of distributing available funds in the best interests of science if they did not give careful and critical attention to such matters.

What my council is concerned to ascertain from our grant-awarding committees is whether, at the end of the day, they feel that a significant proportion of truly deserving applications has had to be turned down through lack of resources. So far, I am glad to say, this has not been the case.

Yours faithfully,
R. J. H. BEVERTON

Natural Environment Research Council,
Alhambra House,
London WC2.

Mild Thaw on Disarmament

SIR,—You state, sensibly enough (*Nature*, **225**, 211; 1970), that with regard to strategic arms limitation, "Relations with the nuclear pigmies—Britain, France and China—are also a complication, if only because nobody can at this stage commit himself to permanent restraint in nuclear weapons when there is no certainty that smaller powers will not seek to become top dogs". Certainly; but also vice versa: few among the "nuclear pigmies" (in esse or posse) can "at this stage commit [themselves] to permanent restraint in nuclear weapons when there is no certainty that" the nuclear giants "will not seek to become top dogs" in the nuclear condominium sense. This is the lesson of the non-proliferation treaty negotiations, and Americans and Russians had better not forget it. If, as *Die Welt* reported two weeks ago, there is a Russian–American plan not to consider Russian medium range strategic missiles until agreement has been reached and put into effect on intercontinental missiles, target states of those medium range strategic missiles—for example, France, United Kingdom, Japan, India, etc.—are unlikely to commit themselves to much "permanent restraint". This fact may well complicate negotiations at Vienna, but it will not go away merely because it is inconvenient.

Yours faithfully,
ELIZABETH YOUNG

100 Bayswater Road,
London W2.

Cover-to-cover Translation

SIR,—Abstracts as a form of journal publication from which subscribers would order full texts as needed are mentioned by your geomagnetism correspondent (*Nature*, **224**, 750; 1969) as a possible solution for meeting cover-to-cover translation problems in geophysics.

Such a scheme has been used for some twenty oriental vernacular journals at the Air Force Cambridge Research Laboratories (AFCRL) since 1962. Abstracts are made for each single number of each journal as received, and are circulated to AFCRL scientists. The individual scientist then requests full translation of those articles whose abstracts appear pertinent to his interests. Abstracts from any one journal are eventually bound together and classified by subject subdivisions in order to provide a desk tool for retrospective search. One such oriental abstract translation publication which is available to the public is *Acta Meteorologica Sinica; translated titles and abstracts from volume 27 (1956) through volume 35 (1965)*, published as AD 667 520. There are 360 articles abstracted in this publication, of which 69 (19 per cent) have been requested in full translation.

Your geomagnetism correspondent also suggests that cover-to-cover translation is not the most economical way of bringing Russian work to the attention of western scientists. However, AFCRL records of articles requested in xerographic copy show that the cover-to-cover translation of *Astronomicheskii Zhurnal* is the second most heavily used journal out of a total of 57 astronomical journals used during 1964–66. Of the 119 users of these 57 astronomical journals, 29 users (15 per cent) requested 106 articles from this fully translated journal. In this case, response time and costs would be greater for an abstract and translation cycle than for a cover-to-cover subscription, as the approximately $50 subscription cost would hardly cover the cost of one translation.

The current difficulties encountered by the American Geophysical Union in its cover-to-cover translation programme may therefore be difficulties specific to an individual discipline rather than to all disciplines. Among factors that appear relevant are reader population sizes among different disciplines and the related number of institutions carrying programmes in these disciplines. This raises some interesting questions about the relationship of disciplines to the need for subsidizing cover-to-cover translation programmes.

Yours faithfully,

OLE V. GROOS

AFCRL Research Library.

Numerical Notation: Decimalization

SIR,—The suggestion of Molyneux (*Nature*, **224**, 1237; 1969) that a number such as 12,300,000 could conveniently be written as "1·23 *D*7" and spoken as "one point two three deka seven" supports the earlier suggestion of Duffin as reported by Synge[1] and differs from it only in the use of "deka" and "deci" rather than "up" and "down" to indicate respectively positive or negative powers of ten.

Such systems, however unpalatable at first sight, lead to a great simplification in numerical notation avoiding both the need to devise[2] new prefixes to indicate multiplication by powers of ten higher than the current tera (10^{12}) or lower than atto (10^{-18}) and also the ever present and regrettable urge to invent new names for multiples or sub-multiples of the primary Système International (SI) units. Equally, the current ambiguities[3] of the terms billion and trillion could disappear from the international scene.

The indicators "up" and "down" are probably more graphic and therefore more readily assimilated than "deka" and "deci". On the other hand, the classical derivation of the latter would render them readily recognizable in other languages: but this is not likely to be material as the indicators "up" and "down" would always be better translated into the language used for the associated numerals in order to form a unified whole for the number expressed.

We are already accustomed to breaking down numbers into groups of three numerals and this facility could be retained by using powers of 10 in multiples of three only, thus

12,300,000 would be said as "twelve point three up six",

1,230,000 would be said as "one point two three up six",

but 123,000 would be said as "one hundred and twenty-three up three".

Yours faithfully,

F. W. DERWENT

National Coal Board,
Ashby Road,
Stanhope Bretby,
near Burton-upon-Trent.

University News

Mr Denis R. Towill has been appointed to the newly established chair in engineering production in the **University of Wales Institute of Science and Technology.**

Appointments

Philip E. Culbertson has been designated director of the **Advanced Manned Missions Program** in the National Aeronautics and Space Administration's Office of Manned Space Flight.

Announcements

The **Neill Prize of the Royal Society of Edinburgh** for 1967–69 has been awarded to **Dr Ann R. Sanderson** for her contributions to taxonomic zoology.

The president and council of the **Royal Astronomical Society** have made the following awards: the Gold Medal to **Dr Horace W. Babcock,** director of the Mount Wilson and Mount Palomar Observatories; the Eddington Medal to **Professor Chushiro Hayashi,** professor of physics, Kyoto University.

ERRATUM. In the paper "Genetics of NADP Isocitrate Dehydrogenase in *Paramecium aurelia*" (*Nature*, **225**, 181; 1970), line 16 on page 182 should read "heterozygote pattern (IDH$_m$ 1–2) is consistent with".

ERRATUM. In the article "The Moon at Houston" (*Nature*, **225**, 321; 1970), the second sentence under the sub-heading Chemical Composition on page 326 should read: "Of the ninety-two elements in the periodic table, results are now available for seventy-nine".

Sabbatical Itinerants

In the hope of providing some practical assistance in the good cause of mobility between laboratories, *Nature* advertises the needs for housing of families about to take up periods of sabbatical leave. To begin with, no charge will be made for advertisements like this. It is hoped that a period of experiment will show what form these advertisements could most usefully take and whether they are effective.

Vacant: House in London, Ontario, Canada, for 12 months from mid-August 1970. Fully furnished, 4 bedrooms, 2 bathrooms, living room, dining room, kitchen, den, playroom, utility room. All necessary appliances, linen, dishes, etc. On 100 foot × 150 foot lot about 1 mile from University of Western Ontario. Please contact Professor Miles H. A. Keenleyside, Department of Zoology, University of Western Ontario, London, Canada.

Vacant: Large 3-bedroom, well furnished flat in Brooklyn, New York, with modern kitchen. Rapid transit time 30 minutes to mid-Manhattan. Opposite Park, Botanic Gardens, Public Library and Museum. For 9–12 months from September 1, 1970. $215/month. Please contact R. Pollack, 135 Eastern Parkway, Brooklyn, New York 11238.

Wanted: Furnished house or flat for New Zealand lecturer and family, 3 double bedrooms minimum, from beginning of March to mid-April, in Oxford, Wantage area. Please contact Dr J. Loutit, MRC Molecular Genetics Unit, Department of Molecular Biology, University of Edinburgh, King's Buildings, Mayfield Road, Edinburgh EH9 3JR.

British Diary

Monday, February 2

Electronic Measurement Related to Fundamental Standards (5.30 p.m. discussion) Institution of Electrical Engineers, at Savoy Place, London WC2.

Ergonomics—Human Factors in Equipment Design (7 p.m.) Mr D. Beevis, Institution of Electrical Engineers, at the Royal Star Hotel, Maidstone, Kent.

Live-line Working on Distribution Systems (5.30 p.m. discussion) Institution of Electrical Engineers, at Savoy Place, London WC2.

The Structure of the Chemical Industry by 1980 (6.30 p.m.) Mr M. C. Hyde, Society of Chemical Industry; and the Industrial Marketing Research Association, at 14 Belgrave Square, London SW1.

Theory of Emulsion Polymerization (7 p.m.) Mr D. Kinsler, Oil and Colour Chemists' Association, at Hull College of Technology.

Tuesday, February 3

Chimaeras in Mouse and Man (5.30 p.m.) The Hon. Dr Anne McLaren, University of London, at the Royal Veterinary College, Royal College Street, London NW1.

Developments in British Hydrography Since the Days of Captain Cook (5.15 p.m.) Rear-Admiral G. S. Ritchie, CB, DSC, Royal Society of Arts, Commonwealth Section, at John Adam Street, Adelphi, London WC2.

Dispersive Acoustic Devices (5.30 p.m.) Dr D. P. Morgan and Mr W. S. Mortley, Institution of Electrical Engineers, at Savoy Place, London WC2.

Expanded Polymers, Mr D. Pannell; **Microwave Heating Applied to the Rubber Industry,** Mr P. A. Wincott (6.30 p.m.) Institution of the Rubber Industry, at the Surrey Arms, Morden Road, Mitcham.

Experience with Area Control of Road Traffic in Glasgow and West London (5.30 p.m.) Mr J. A. Hillier and Mr B. M. Cobbe, Institution of Electrical Engineers; and the Automatic Control Group of the I.Mech.E., at Savoy Place, London WC2.

New Concepts of the Function of the Lymphatic System in the Swollen Leg (5.30 p.m.) Mr J. S. Calnan, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Eighth of fifteen lectures on "The Scientific Basis of Medicine".)

The Adsorption Recovery of Solvents from Moist Air (7 p.m.) Mr H. J. Abrams, Mr G. Jones and Mr C. H-T. Koo, Institution of Chemical Engineers, at the Oaklands Hotel, Hoole Road, Chester.

The Comfort of Unreason in Archaeology (8 p.m.) Dr Glyn Daniel, in the Middleton Hall, University of Hull.

Wednesday, February 4

Biochemistry of Bacterial Walls in Relation to the Membrane (4.30 p.m.) Professor Jean Marie Ghuysen, Medical Research Council, at the National Institute for Medical Research, Mill Hill, London NW7.

Colour in Situ (3 p.m.) Mrs P. Brooke, Mrs P. Pirie, Mr D. Phillips and Mr M. J. Thomas, Colour Group (Great Britain), in the Physics Building, Imperial College, London SW7.

Going Metric in the UK Petroleum Industry (5.30 p.m.) Mr A. Haddock, Institute of Petroleum, at 61 New Cavendish Street, London W1.

Medical Illustration (1 p.m.) Mr E. Gaskell, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

Modern Techniques in High-voltage Cable Laying (7.30 p.m.) Mr D. J. Skipper and Mr E. P. C. Watson, at the CEGB, Guildford, Surrey.

Optical Communications through Glass Fibres (7 p.m.) Professor W. A. Gambling, Institution of Electronic and Radio Engineers, at Guildford Technical College.

Passive Satellite Communications (6 p.m.) Mr R. L. Harris, Institution of Electronic and Radio Engineers, at 9 Bedford Square, London WC1.

Recent Developments in the Fluid Transport of Granular Materials in Pipelines (5.30 p.m.) Dr R. A. Duckworth, University of London, at King's College, Strand, London WC2.

Science and Race (1.15 p.m.) Professor M. Banton, University of London, at Queen Elizabeth College, Campden Hill Road, London W8.

The Open University (6 p.m.) Dr Walter Perry, OBE, Royal Society of Arts, at John Adam Street, Adelphi, London WC2.

The Teaching of Hydrodynamic Lubrication Using Scaled Models, and Optical Elastohydrodynamics (6 p.m.) Mr A. Cameron, Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

The Testing of Servomechanisms for Development and Maintenance (5.30 p.m. discussion) Institution of Electrical Engineers, at Savoy Place, London WC2.

Thursday, February 5

Engineering and the Science Research Council (5.30 p.m.) Sir Brian Flowers, FRS, Institution of Electrical Engineers, at Savoy Place, London WC2.

Functional Coatings for the Packaging Industries (6.30 p.m.) Mr J. Howarth-Williams, Oil and Colour Chemists' Association, at the Royal Turks Head Hotel, Grey Street, Newcastle upon Tyne.

Have the Full Horrors of Metrication Dawned on the Steam Plant World ? (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Metabolism of Pyrrolizidine Alkaloids and Its Relation to their Biological Effects (5 p.m.) Mr A. R. Mattocks, University of London, at the Middlesex Hospital Medical School, Mortimer Street, London W1.

New and Traditional Refrigeration Systems for Air-Conditioning (6 p.m.) Mr J. H. Allen, Institute of Refrigeration, at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London SE1.

Physiological Measures in Psychiatry (5.30 p.m.) Dr M. H. Lader, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Ninth of fifteen lectures on "The Scientific Basis of Medicine".)

Pick-up Design (7 p.m.) Institution of Electronic and Radio Engineers; and the Institution of Electrical Engineers, at the Shrewsbury Arms Hotel, Market Street, Rugeley, Staffs.

Radiometric Standards (2.30 p.m.) Society for Analytical Chemistry, Radiochemical Methods Group, in the Lecture Room of the Laboratory of the Government Chemist, Cornwall House, Stamford Street, London SE1.

Reproduction in the Giant Pacific Octopus (4.30 p.m.) Professor T. R. R. Mann, FRS, Royal Society, at 6 Carlton House Terrace, London SW1.

The Making of Mountains (1.20 p.m.) Dr R. Mason, University of London, in the Botany Theatre, University College London, Gower Street, London WC1.

Friday, February 6

Some Aspects of Direct Television Reception from Satellites (5.30 p.m.) Mr K. G. Freeman, Mr R. N. Jackson, Mr P. L. Mothersole and Mr S. J. Robinson, Institution of Electrical Engineers, at Savoy Place, London WC2.

The Role of Excimers, Exciplexes and Electron Transfer in Photochemical Reactions (1 p.m.) Dr S. Davidson, Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

Saturday, February 7

Appreciating the Countryside—Nature Trails and Field Museums in Britain and America (3.30 p.m.) Mr G. Stansfield, Inner London Education Authority, at the Horniman Museum, London Road, Forest Hill, London SE23.

Microcirculation of the Skin, Mr T. J. Ryan, Miss K. A. Grice, Mr C. A. Ramsay, Mr J. Morley, Mr T. J. Williams and Mr W. Hartson; **Other Microcirculation Topics,** Mr S. M. Blench, Mr A. L. Stalker, Mr L. J. Brown, Mr J. N. Mehrishi and Mr W. L. Whitehouse (2 p.m.) British Microcirculation Society, at Queen Mary's Hospital, Roehampton, London SW15.

Monday, February 9

A Volunteer at Masada (5.30 p.m.) Miss Katherine Blair, Royal Institution, at 21 Albemarle Street, London W1.

Colour Television Receiver Design and Maintenance (6 p.m.) Mr G. D. Barnes, Institution of Electronic and Radio Engineers; and the Institution of Electrical Engineers, at the University of Strathclyde, Glasgow.

Polymers in the Year 2000 (7.30 p.m.) Professor C. E. H. Bawn, CBE, FRS, Institution of the Rubber Industry, at the Donnan Laboratories, The University, Liverpool.

Techniques of Mask-making (2.30 p.m. colloquium) Institution of Electrical Engineers, at Savoy Place, London WC2.

HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire.................................**£14.0.0** each
United States of America........(by air freight)............**$48** each
Canada..........................(by air freight)..........**$52** each
Elsewhere overseas by surface mail....................**£14.0.0** each

(Charge for delivery by air mail on application)

*Shorter periods *pro rata.* (Minimum three months.)

UNIVERSITY COLLEGE OF NORTH WALES

BANGOR

DEPARTMENT OF PURE MATHEMATICS

Applications are invited for the post of LECTURER IN PURE MATHEMATICS.

Salary will be at a suitable point on the scale £1,240 by £115 to £2,850.

Further particulars of this post may be obtained from the Secretary and Registrar and applications (two copies), giving details of age, qualifications and experience together with the names and addresses of three referees, should be sent to reach the Secretary and Registrar by February 21, 1970. (386)

UNIVERSITY COLLEGE OF TOWNSVILLE

DEPARTMENT OF BIOLOGICAL SCIENCES

Applications are invited for the position of

TECHNICAL OFFICER GRADE I

(Curator of Microscopes)

An experienced microscope and optical instrument mechanic is required to establish a microscope curating service and to set up a small workshop for tool and precision instrument assembly and repair.

Present microscope stocks, manufactured by Zeiss, Leitz, Wild, Olympus, Vickers, Zeiss Jena, Nikon range from student monoculars to photomicroscopes.

Applicants must have served a recognized engineering apprenticeship, preferably with an optical instrument maker and must have recent experience in producing or servicing optical instruments.

Removal expenses and fares will be provided through the Australian Commonwealth Government Assistant Migrant Scheme.

The salary payable will be within the ranges $A1,138 to $A4,455 per annum. Persons holding appropriate Degree or Diploma receive an additional $A300 per annum.

Applications, giving full details of age, qualifications and experience, together with references or the names of referees, should be sent to:

The Staff Officer,
University College of Townsville,
P.O. Box 999,
TOWNSVILLE, Q. 4810,
AUSTRALIA.

with whom applications close on February 28, 1970. (370)

UNIVERSITY OF TORONTO

TORONTO, CANADA

The Institute for Aerospace Studies has a vacancy effective July 1, 1970, or earlier in the field of aerodynamic noise at the ASSISTANT or ASSOCIATE PROFESSOR level. Candidates should have a Ph.D. with strength in both experimental and theoretical aspects of the field. Duties would include teaching and research (with supervision of graduate students) to complement the existing programme on jet noise and sonic boom.

Applications should be sent to H. S. Ribner, Institute for Aerospace Studies, University of Toronto. A curriculum vitae, detailing background and publications, should be included. Letters of reference are desirable but not essential, and material will be held in confidence if requested. Interviews will be held by Dr. Ribner at Cumberland Hotel, Marble Arch, London, W.1, on February 9, 1970, between 10 a.m. and 4 p.m. (376)

SOUTH AFRICA

"geologists paradise"

is an epithet justified by large varieties of geological formations and rich mining deposits together with climate ideal for outdoor work.

The Geological Survey Department of the South African Government now offers the following opportunities for suitably qualified scientists:

GEOLOGISTS

holding at least a B.Sc. (Hons) degree (or equivalent four year degree) in geology, to deal with geological mapping, and field and laboratory investigation, on one or other specialised area.

GEOPHYSICISTS

with at least a B.Sc. (Hons) or equivalent four year degree in physics/geology, to work in the field on geophysical surveys in search of water and minerals, and on data reduction.

In addition to the indicated work ample opportunities will be available for research.

Initial appointment will be on an extendible three-year contract basis, while permanent pensionable positions could be available on the attainment of South African citizenship.

A salary in the region of £1,750–£2,625 will be offered, together with field and travelling allowances, for a five-day working week. Fringe benefits include generous vacation and sick leave, vacation bonus and medical benefit scheme. Full air or sea passage will be paid for successful applicants and their dependants.

Applications, or requests for further information, should be sent to the

Chief Migration Officer,
South African Embassy,
Trafalgar Square,
London W.C.2.

(415)

For further Classified advertisements see page iiib

Beecham Research Laboratories Walton Oaks Tadworth Surrey

Biochemists

to be employed in Lipid Metabolism Studies. These are new appointments and the successful applicants will work within a newly formed Project Group on investigations into nutritional and metabolic diseases in animals and humans. This will involve fundamental studies in the fields of lipid and carbohydrate metabolism.

Candidates should have a good honours degree in Biochemistry and either a further degree or experience in biochemical research. Some training in physiology and a background in nutritional research, although not essential, would be an advantage. The successful applicants will be joining a multidisciplinary team of scientists and will be given considerable scope to work on their own initiative.

A good starting salary will be offered and reviewed regularly. Beecham Research Laboratories is part of the Beecham Group, for whose generous non-contributory fringe benefits, including profit sharing worth an additional 10% to 11% of salary, and pension scheme with life coverage, the successful candidates will qualify. The laboratories are situated in a pleasant area of Surrey within easy reach of London, and consideration may be given to removal assistance.

Applications should be sent to: **Head of Personnel Department, Beecham Research Laboratories, Brockham Park, Betchworth, Surrey.** (436)

BIOCHEMICAL RESEARCH

TEAM LEADER

Biorex Laboratories Ltd. are seeking a Senior Biochemist with several years' postdoctoral experience who will recruit and lead a small research team in biochemistry. The team will co-operate with established teams of pharmacologists and chemists in the development of compounds of therapeutic importance and in the elucidation of their mode of action.

The research organization of Biorex Laboratories already collaborates extensively with various Universities and the successful applicant will be expected to foster and extend such collaboration.

Interested persons are invited, in the first instance, to write for additional information to **The Director of Research, Biorex Laboratories Ltd., Biorex House, Canonbury Villas, London, N.1.** (442)

UNIVERSITY COLLEGE CARDIFF

DEPARTMENT OF PSYCHOLOGY

RESEARCH ASSISTANT

Applications are invited from suitably qualified persons for the post of RESEARCH ASSISTANT. The person appointed will work with Dr. J. S. Dimond on a project supported by the Medical Research Council on "The Role of the Cerebral Hemispheres in the Control of Human Performance." The post carries a salary of £1,000 by £100 to £1,200. The appointment will be initially for three years.

Letter of application, quoting Ref. No. ADV/N, together with a full curriculum vitae and the names and addresses of two referees should be submitted to the Registrar, University College, Cathays Park, Cardiff, from whom further particulars of the Department may be obtained, not later than February 28, 1970. (444)

UNIVERSITY OF LIVERPOOL

DEPARTMENT OF BOTANY

Applications are invited for the post of LECTURER IN ECOLOGY in the Department of Botany. Preference will be given to candidates with interests in applied aspects of the ecology of terrestrial environments, particularly the effects of pollution by industrial activity or pesticides and herbicides or the problems of derelict land. The duties of the post will commence on 1st October, 1970. The initial salary will be within the range £1,240–£2,850 per annum.

Applications, stating age, qualifications and experience, together with the names of three referees, should be received not later than 9th March, 1970, by the Registrar, The University, P.O. Box 147, Liverpool L69 3BX, from whom further details may be obtained. Please quote Ref.: RV/5680/N. (422)

UWIST CARDIFF

UNIVERSITY OF WALES INSTITUTE OF SCIENCE AND TECHNOLOGY

APPLIED PHYSICS DEPARTMENT

LECTURER IN ELECTRONICS

required to assist in teaching students preparing for the B.Sc.(Tech.) and M.Sc./Diploma in Electronics.

Applications would be particularly welcome from persons with experience of semiconductor physics of particular application to integrated circuits and with practical experience in this field.

Salary for initial appointment in the range £1,240 by £115 to £1,700. Full salary scale £1,240 to £2,045 (bar) to £2,850.

Application forms (to be returned by February 23 quoting Ref. N) and further particulars may be obtained from the Personnel Officer, UWIST, Cardiff, CF1 3NU. (410)

WEST HAM COLLEGE OF TECHNOLOGY

ROMFORD ROAD, LONDON, E.15

RESEARCH TECHNICIAN

required to assist project in association with the National Physical Laboratory and financed by the Ministry of Technology.

The work will involve evaporation of films in ultra-high vacuum.

Starting salary, £1,250 per annum.

Applications giving full details of age, qualifications and experience, together with the name of a referee, should be sent as soon as possible to the Head of the Physics Department. (426)

ROWETT RESEARCH INSTITUTE

BUCKSBURN, ABERDEEN, AB2 9SB

LARGE ANIMAL CALORIMETRY

The Calorimetry Section of the Physiology Department of the Institute is to be considerably expanded in size and staff and applications are invited from suitably qualified biochemists or physiologists for its Headship. The post is graded Principal Scientific Officer (£2,599 to £3,596) but for the exceptional candidate the Senior P.S.O. grading (£4,045 to £4,620) would be considered. Superannuation under F.S.S.U. Applicants will be expected to take part in the planning of the expansion as well as to undertake research into feed energy utilization by pigs, cattle and sheep.

Applications, which should include the names of three referees, should be sent to the Secretary of the Institute by February 28, 1970 (possible extension for overseas candidates). Further details may be obtained on request. (343)

MEMORIAL UNIVERSITY OF NEWFOUNDLAND

Invites applications for the position of

DEAN OF SCIENCE

Science Departments include Biochemistry, Biology, Chemistry, Geology, Mathematics, Physics and Psychology with an academic staff totalling 100. All Departments offer the M.Sc. and five have Ph.D. programmes. Special interests of the various Departments include: cell biochemistry, pollution-related biology, NMR and ESR spectrometry, solid earth geophysics, Appalachian geology, laser physics, and topology. Interdisciplinary studies are emphasized, particularly those bearing on the problems and resources of the Canadian Atlantic Region—and these have lead to the establishment of the Institute for Research in Human Abilities, the Centre for Environmental Biology and the Marine Sciences Research Laboratory.

A vigorous professional scientist is sought for this newly created post, preferably with administrative experience and an extensive background in teaching and research. The salary will be competitive.

Applications should include a full curriculum vitae and the names of three referees and should be addressed to: The President, Memorial University of Newfoundland, St. John's, Newfoundland, Canada.

A copy of applications should also be sent to the Secretary-General, Association of Commonwealth Universities (Appts.), 36 Gordon Square, London, W.C.1. from whom information about the University may be obtained. **(324)**

UNIVERSITY COLLEGE LONDON

Applications invited for two posts of LECTURER and TEMPORARY LECTURER (with prospects of permanent appointment) in Department of MATHEMATICS. Applicants should have a research interest in some branch of Pure Mathematics, to commence on October 1, 1970. Salary, according to age and experience, on scale £1,240 to £2,850, plus £60 London Allowance, p.a.; F.S.S.U.

Applications as soon as possible to the Secretary, University College London, Gower Street, W.C.1, from whom further particulars may be obtained. (433)

UNIVERSITY OF WALES

UNIVERSITY COLLEGE OF SWANSEA

SECOND CHAIR OF GEOGRAPHY

Applications are invited for the Second Chair of Geography in the department of Geography.

Further particulars, quoting reference No. B6, may be obtained from the Registrar, University College of Swansea, Singleton Park, Swansea, Glam. SA2 8PP, by February 21, 1970.

ANEURIN DAVIES,
Registrar.
(383)

CSIRO

RESEARCH APPOINTMENTS

AUSTRALIA

DIVISION OF PLANT INDUSTRY
TOBACCO RESEARCH INSTITUTE

GENERAL The Tobacco Research Institute at Mareeba is a unit of the Division of Plant Industry of the Commonwealth Scientific and Industrial Research Organization and is located 40 miles inland from Cairns, North Queensland, in the centre of a district in which tobacco growing under irrigation has expanded rapidly in recent years. Work at the Institute includes physiological, nutritional, and agronomic studies to determine factors responsible for the yield and quality of the cured tobacco leaf. The Institute has excellent facilities for laboratory and field research, including well-equipped laboratories, glass-houses, library and experiment station. In addition it has strong links with the headquarters of the Division in Canberra, A.C.T., which is engaged in research in many fields of plant biology.

Secondary education is available and housing will be provided at a nominal rental in the the case of married male appointees. Applications are invited for appointment to the following research positions.

SOIL CHEMIST (Reference No. 815/83) The growth of an exhaustive crop such as tobacco combined with the use of irrigation water to extend the growing season, has resulted in a decline in soil fertility with a consequent deterioration in the quality of the tobacco leaf being produced. The appointee will be required to investigate the possibility of preventing further deterioration of these sandy loams, of rehabilitating these soils and studying the contribution of rotation crops to tobacco nutrition under local conditions. The effect of irrigation on the activity of soil micro-organisms, would also be incorporated in the study.

CROP PHYSIOLOGIST—AGRONOMIST (Reference No. 815/82) Mainly because of disease and water availability, a pattern of tobacco production has been established involving field planting in the cooler months of the year, and harvesting in November-December. At this latter time the upper section of the plant is developing while the lower is senescing. These conditions require a delicate balance of nutrition to prevent deficiencies or excesses. With the introduction of disease resistant varieties and a possible shift in desired leaf types, changed planting times are being investigated with planting in late summer. An officer is required to participate in studies of the differences in leaf development under the two different regimes.

QUALIFICATIONS Applicants should have a Ph.D. degree in an appropriate field or postgraduate research experience of equivalent standard and duration, supported by satisfactory evidence of research ability.

SALARY Depending upon qualifications and experience, the appointments will be made within the salary range of Research Scientist, $A6,139–$A7,789 p.a., or Senior Research Scientist, $A8,105–$A9,448 p.a. Salary rates for women are $A428 p.a. less than the corresponding rates for men. In addition to salary a District Allowance of $A140 p.a. (Married) and $A70 p.a. (Single) is payable.

CONDITIONS The appointments will be initially for a fixed term of three years, after which, if mutually desired, either an extension of tenure or appointment for an indefinite period will be considered. The appointments will be conditional upon passing a medical examination and an initial probationary period of twelve months may be specified. An indefinite appointment carries with it Commonwealth Superannuation Fund or Provident Account privileges. Fares paid for the appointee and his dependent family.

Applications, quoting the appropriate reference number, and stating full name, place, date and year of birth, nationality, marital status, present employment, details of qualifications and experience, together with the names of not more than four persons acquainted with the applicant's academic and professional standing, should reach:

Mr. R. F. Turnbull,
Chief Scientific Liaison Officer,
Australian Scientific Liaison Office,
64 Kingsway, LONDON, W.C.2. by the *27th February, 1970.*

Applications in U.S.A. and Canada should be sent to The Scientific Attaché, Australian Embassy, 1601 Massachusetts Ave. NW, WASHINGTON DC 20036.

(396)

UNIVERSITY OF LEICESTER

LECTURER IN PHYSIOLOGY

Applications are invited for a LECTURESHIP in the DEPARTMENT OF PHYSIOLOGY in the School of Biological Sciences. Initial salary according to qualifications and experience on scale £1,240 to £2,850 a year, with F.S.S.U. membership. An appointment might be made in the Senior Lectureship grade (maximum £3,670 a year) if a suitable applicant presented himself.

Further particulars from the Registrar, to whom applications should be sent by February 7. (315)

BIOCHEMISTRY DEPARTMENT

ROYAL DENTAL HOSPITAL SCHOOL

LEICESTER SQUARE, LONDON, W.C.2

required to assist in full-time research. Experience in Auto-Analyser work, chromatography, fluorimetry or protein chemistry techniques an advantage. Appointment on Technician/Senior Technician scale according to age, experience and qualifications.

Apply to Head of Biochemistry Department. (342)

THE ROYAL HORTICULTURAL SOCIETY

A vacancy will shortly occur on the scientific staff of the Society at Wisley for which applications from graduates, men and women are invited. The duties of the post will be to assist the Plant Pathologist in advisory work and in carrying out scientific investigations on plant diseases and disorders. The successful applicant will be expected to take up the appointment as early as possible. The salary, reviewed annually, will be related to qualifications and experience. The post is pensionable.

Applications, with details of qualifications, experience and the names of two persons to whom reference may be made should reach the Secretary, The Royal Horticultural Society, Vincent Square, London, S.W.1, not later than Monday, March 16. (462)

UNIVERSITY OF QUEENSLAND

AUSTRALIA

POSTDOCTORAL RESEARCH FELLOW IN BIOCHEMISTRY

Applicants should have a Ph.D. with a First Class Honours degree in either Biochemistry or Chemistry. The successful applicant will work within the Enzymology group of the Department of Biochemistry, which is currently looking at the mechanism of action of a broad spectrum of hydrolytic enzymes.

A Postdoctoral Research Fellow is eligible for Superannuation similar to F.S.S.U., and salary will be at a rate of up to $A5,650 per annum.

Applications should include the names and addresses of three referees and state age, educational qualifications and experience and be forwarded to the Registrar, University of Queensland, St. Lucia, Brisbane, Queensland 4067, Australia by February 27, 1970. (413)

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL

DENMARK HILL, S.E.5

Applications are invited for the following appointments in the Liver Research Unit, which includes the Medical Research Group on the Metabolism and Haemodynamics of Liver Disease:

(1) BIOCHEMIST (lecturer grade £1,645 to £2,105 per annum).

(2) BIOCHEMIST (Hospital biochemist scale £1,224 to £1,513 per annum).

Current research projects include studies of hepatic enzyme induction and bilirubin metabolism, factors controlling iron absorption and methods for treating acute liver failure, including transplantation. Further particulars may be obtained from Dr. Roger Williams.

Applications, stating age, qualifications and experience, with names of two referees, to the Secretary of the Medical School by February 7, 1970. (394)

UNIVERSITY OF ABERDEEN

LECTURER IN PHARMACOLOGY

Applications are invited for this newly created post. Experience in biochemical pharmacology or training in biochemistry required. Salary on scale: £1,240 to £2,850 with initial placing according to qualifications and experience. Superannuation (F.S.S.U.) and removal allowance.

Further particulars from the Secretary, the University, Aberdeen with whom applications (eight copies), should be lodged by February 28, 1970. (X403)

THE AGRICULTURAL RESEARCH COUNCIL has a vacancy for an Assistant Experimental Officer/Experimental Officer in the Unit of Invertebrate Chemistry and Physiology at the University of Sussex. The successful candidate will assist in the development of bioassays of insect hormones and the study of their mode of action in the adult insect. Work will involve the handling of insects, micro-assay and biochemical analyses, including the use of radio-isotopes. Detailed instruction will be given, but the candidate should be familiar with current biochemical techniques. Opportunities for independent research will arise. Qualifications. Candidates over 22 should have, or expect to obtain, a pass degree, H.N.C. or equivalent qualification. Candidates under 22 who have at least two G.C.E. "A" level passes in appropriate science subjects may also be considered. Salary. A.E.O., £683 per annum (at age 18); £940 per annum (at age 22); £1,208 per annum at age 26) rising to £1,454. E.O., £1,590 per annum to £2,006 per annum.—Applications should be sent to: Mr. S. E. Lewis, A.R.C. Unit of Invertebrate Chemistry and Physiology, Chemical Laboratory, University of Sussex, Falmer, BRIGHTON, BN1 9QJ, Sussex. (355)

UNIVERSITY OF ABERDEEN

EXPERIMENTAL PHYSICS

Applications are invited for post of RESEARCH FELLOW for work in BOTANY Department, supported by N.E.R.C. on transfer of energy and matter in forest canopies. Degree in Physics or Engineering or allied sciences with Ph.D. or other postgraduate experience; interest in aerodynamics or heat transfer and computing desirable.

Salary in range £1,240 to £2,850. Superannuation (F.S.S.U.). Appointment initially for two years.

Further particulars from The Secretary, The University, Aberdeen, with whom applications (two copies), should be lodged by February 28, 1970. (457)

WELSH NATIONAL SCHOOL OF MEDICINE
(University of Wales)

RESEARCH SCIENTIST

Graduate, non-medical (e.g., physicist, chemist, physiologist), preferably with research experience, required to join a team studying the effects of automatic ventilation of the lungs in anaesthetized animals. Appointment up to three years and at a salary within the scale £1,240 to £2,045. Starting point according to qualifications and experience. Federated Superannuation System for Universities.

Further details from and applications to Department of Anaesthetics, Royal Infirmary, CARDIFF, CF2 1SZ. (452)

UNIVERSITY OF NATAL

DEPARTMENT OF CHEMISTRY, DURBAN

Applications are invited from suitably qualified and experienced persons for appointment to the post of LABORATORY TECHNICIAN (INSTRUMENTS). Applicants should hold a City and Guilds Science Laboratory Technicians' Advanced Certificate or equivalent trade certificate and should have an interest in modern chemical instrumentation particularly UV and IR spectrophotometers and gas chromatographs. The annual salary scale attached is R2,040 by R120 to R3,120 (£1,185 to £1,813). In addition a pensionable allowance of 10 per cent of salary is payable, this allowance will be increased to 15 per cent with effect from April 1, 1970.

Application forms are obtainable from the Secretary-General, Association of Commonwealth Universities (Appts), 36 Gordon Square, London, W.C.1, and application must be lodged not later than March 20, 1970. (446)

OXFORD UNIVERSITY

PHYSICAL CHEMISTRY LABORATORY

Applications are invited for a post-doctoral research assistant in chemical spectroscopy (mainly infra-red and photoelectron) in the salary range £1,200 to £1,600, starting October next (or earlier).

Applications, giving qualifications and the names of two referees, should be sent as soon as possible to Professor Sir Harold Thompson, Physical Chemistry Laboratory, South Parks Road, Oxford. (460)

LISTER INSTITUTE OF PREVENTIVE MEDICINE

(UNIVERSITY OF LONDON)

Required immediately—Post-doctoral Research Worker for studies on the metabolism, especially biosynthesis, of glycosphingolipids in mammalian tissues. Previous experience in lipid biochemistry desirable but not essential. The work is supported by the M.R.C. Salary up to £1,610, plus £60 London Allowance per annum and F.S.S.U. benefits.

Applications, with the names of two referees, should be sent to the Secretary, at Chelsea Bridge Road, London, S.W.1. (461)

POST-DOCTORAL RESEARCH FELLOW required in Department of Clinical Pharmacology to work on drug metabolism in man. Salary in range £1,480 to £1,690 per annum.—Applications to the School Secretary, Royal Postgraduate Medical School, Hammersmith Hospital, London, W.12, quoting ref.: 2/458. (464)

THE UNIVERSITY OF LEEDS

DEPARTMENT OF EARTH SCIENCES

M.Sc. courses in
GEOCHEMISTRY
GEOPHYSICS
ENGINEERING GEOLOGY AND GEOTECHNICS

Applications are invited for entry to the above postgraduate courses which lead to the degree of M.Sc. by examination. The courses are for 12 months, beginning on October 1, 197[illegible] and have been approved for the award of Advanced Course Studentships.

The entry requirements are a 1st or 2nd Class Honours degree in an appropriate subject: Geology or Earth Sciences, Chemistry, Physics, Mathematics, Civil Engineering or Mining, or a combined scheme of study which includes at least one of these subjects.

The course in Engineering Geology and Geotechnics is run jointly with the Department of Civil Engineering and the course in Geophysics is run in conjunction with the Department of Mining and Mineral Sciences.

Further details and application forms can be obtained from the **Secretary, Department of Earth Sciences, The University, Leeds LS2 9JT.** (465)

DALHOUSIE UNIVERSITY

DEPARTMENT OF GEOLOGY

HALIFAX, NOVA SCOTIA, CANADA

Applications are invited for an appointment in GEOPHYSICS and an appointment in GEOCHEMISTRY tenable in the Department of Geology. Successful candidates will be asked to teach at undergraduate and graduate levels, and develop graduate research programmes. If desirable, joint appointments in the Department of physics or the Institute of Oceanography may be arranged. Applicants with marine backgrounds may be interested in the oceanographic facilities in this area. The positions are tenable from July 1, 1970.

Write for further details, and send copies of curriculum vitae and names of three referees to: The Chairman, Department of Geology, Dalhousie University, Halifax, Nova Scotia, Canada. (405)

RESEARCH ASSOCIATE

B.Sc graduate wanted for research into aspects of coagulation and fibrinolysis, in Melbourne, Australia. Work could lead to Ph.D.

Apply to Dr. H. Ekert, Institute of Child Health, 30 Guildford Street, London, W.C.1. Tel. 242 9789. (381)

RADIOBIOLOGIST

A graduate research worker with interest or experience in mammalian radiobiology and its application to radiotherapy is required for a post in the Churchill Hospital Research Institute. The successful applicant will join an interdisciplinary group studying various aspects of tissue and tumour growth and the effects of ionizing radiation and drugs upon it. Salary according to age, qualifications and experience.

Replies to Dr. R. J. Berry, M.R.C. External Scientific Staff, Radiobiology Laboratory, Churchill Hospital, Oxford. (441)

TECHNICIAN/SENIOR TECHNICIAN I required in Department of Medicine. Some experience in basic immunological techniques, protein electrophoresis and column chromatography desirable. Salary according to qualifications and experience.—Applications in writing to the Secretary, Royal Postgraduate Medical School, Hammersmith Hospital, London, W.12, quoting ref.: 2/466. (463)

SENIOR TECHNICIAN required to operate electron microscope in research department. Experience in maintenance and preparatory techniques essential.—Apply, with full details of age, qualifications and experience, to Dr. H. Stern, Virus Department, St. George's Hospital Medical School, London, S.W.1. (421)

Nature in North America: The *Nature* office in Washington DC opened last week. Contributors in the United States and Canada are invited to submit manuscripts for publication either to the address given below or to the present London office. The intention is that each office will be able to answer inquiries about all manuscripts and other matters, although a strictly symmetrical situation will not obtain until mid-February, from which point, for half a year, the editor of *Nature* will be based in Washington. This is one of several steps by which it is hoped to provide a better service for readers and contributors.

This new Unicam UV Spectrophotometer has been made to meet your requirements

To meet, in fact, the requirements of every UV spectroscopist—whether engaged in research or in routine applications. And that means that the new Unicam SP8000 Ultraviolet and Visible Recording Spectrophotometer is just about the most versatile instrument available. To start with you get superb presentation and reproducibility of spectra on the integral flat-bed recorder. You get dual-absorbance scales of 0-1.0A and 0-0.2A with back-off. You get exceptional scale expansion. There is a large sample compartment and a unique second sample position. There is a whole range of modular accessories for automation. If you want digital print out, results in concentration units, automatic wavelength selection, programme control, automatic sample changing of up to 50 samples—you name it and the likelihood is that the Unicam SP8000 system can do it. The Unicam SP8000 is the latest addition to an outstanding range of UV instruments which includes the SP500 Series 2, the SP700, the SP800 and the award-winning SP3000. To learn more about any of these write to us today.

The new Monroe 820 Calculator

The Monroe 820 introduces a brand new generation in electronic calculators. Smaller, lighter and much more compact, thanks to integrated microcircuits. Simple to operate, priced to fit your budget. Using only four keys more than an adding machine to handle every business calculation in milliseconds.

You can do arithmetic operations in any sequence and there are a host of advanced features including automatic constant multiplier and divisor, automatic decimal point and roundoff, and automatic squaring.

Fourteen digit answers appear sharp and clear in large numerals on the non-glare display screen – plus the running total.

The 820 is ready for work the instant it's switched on and there's no need to clear the calculator.

It all happens in complete silence.

More Flexibility on Drugs

THERE are signs that the Home Office is planning a more liberal revision of the British law on drugs than seemed probable a year ago, when the Home Secretary reacted like a Bourbon to the publication of the report of the committee under Baroness Wootton which recommended, among other things, lighter penalties for offences involving soft drugs such as cannabis. Then, Mr Callaghan went a long way to suggest that the committee's advice was not to be taken seriously. Now, it looks as if the Home Office will publish in the next few weeks proposals for new legislation on drugs which will direct the fullest rigours of the law at those who market illicit drugs, not at those who use them. By all accounts, there will be three categories of drugs in the new bill—hard, soft and softer—and penalties whose severity will be matched to the character of the drug concerned. The possession and presumed use of cannabis will apparently be dealt with more lightly than at present, when it is possible for people to be sent to prison for as much as ten years and fined as much as £1,000. (Cannabis offences under the Dangerous Drugs Act, 1965, led to close on 300 prison sentences a year in the mid-sixties, roughly half of them for periods of between three and six months.) Still less harmful drugs, pep pills, for example, will be dealt with more leniently still. So far, it is not clear how the Home Office will set about making life even harder for those who sell these drugs, but there is some awesome sabre-rattling in the wings. Everything should be clearer by the late spring, though it is only reasonable to wonder whether the Home Office can be right in hoping that its new legislation will be on the statute book before the end of the current parliamentary session in the autumn.

The coincidence of the talk about new British legislation and the somewhat fitful passage of Senator Thomas Dodd's bill through the United States Senate—it remains to be seen what the House of Representatives will make of it—is not conspicuously a marvel. Only a week ago, the United Nations Narcotics Commission in Geneva was putting the finishing touches to its new draft code intended to provide governments with guidance in the design of legislation. The essence of the commission's code is a catalogue of drugs of dependence—"psychotrophic drugs" as they are now called—which it may be sensible to deal with differently under the terms of national legislation. The next step will be consideration of the code by the Economic and Social Council of the United Nations, but long before that process is complete, it may well be that the United States and the United Kingdom will both be provided with legislation that deals differently, and more leniently, with users of cannabis than with users of heroin. That is at least something to be grateful for. The past few years have often made a mockery of the pharmacological characteristics of these and other substances, have dealt harshly with people deserving lighter penalties and have provided too many opportunities for arbitrary action by those who administer the law. The penchant of the British police for smelling out—in one case, at least, almost literally—pop musicians using cannabis, and the tendency for magistrates to regard the sentencing procedure which follows as an opportunity for delivering ill-conceived homilies on the iniquities of a younger generation, has only served further to undermine respect for the law on cannabis. This is probably the strongest argument for dealing differently with cannabis and heroin, as the Home Office now proposes.

Unfortunately, however, this cannot be an end of the process of bringing the law up to date. The revision now proposed may hold the line—as some will describe it—for a few years, but eventually there will have to be a much more radical reconsideration of the proper place of cannabis in modern society. The trouble, of course, is that the illicit cannabis habit has provided modern society with several important challenges so far largely ignored. Unlike many other drugs, especially the hard narcotics, cannabis seems to be comparatively benign. To be sure, there is still a good deal of dispute about the causal relationship between cannabis and hard drugs such as heroin—does the first lead to the second ? It is not, of course, surprising that most heroin addicts have previously smoked pot—poker players usually begin with snap. The possibility that cannabis causes a kind of pharmacological disposition towards heroin has been suggested, but the way in which the majority of cannabis users do not move on to dangerous narcotics suggests that it would be hard to distinguish between pharmacological and social acclimatization. In the past, it may well have been that the application of the same penalties to hard drugs such as heroin and softer drugs such as cannabis tended to lump them all together. Differential penalties should make the distinction more evident to the people most at risk, and may even thus help to dissuade potential addicts from the hard narcotics.

That is an immediate consideration. There remains the problem of how a society which is already well used to several forms of crippling self-indulgence shall justify its continuing refusal to put cannabis, by many tests a comparatively mild form of abuse compared with alcohol and tobacco, on general or even licensed sale. A year ago, Mr Quintin Hogg made the quite sensible if somewhat empirical point that it would be madness to admit yet another social scourge into common currency on the grounds that alcohol and tobacco are already familiar. This is good homespun, but unfortunately it cannot be expected to stand the test of time. The lighter penalties for cannabis usage now in prospect may for a short time ease the sense of conflict between those who use pot and the rest of society, but it will only be a few years before the reputation of cannabis is made to seem as anomalous as it is now. For there is very little likelihood that the new legislation will bring the peddling of pot entirely to a stop—it will merely increase the cost of breaking the law. In the circumstances, it is essential that the problems of cannabis should be regarded in a much more penetrating way than that which has now suggested new legislation.

What should be done? To begin with, there is a great need for more objective understanding of the effects of using cannabis, not merely in the pharmacological sense but in behavioural terms as well. Great though the interest in cannabis has been in recent years, only the surface has been scratched so far. Second, there is a great need of more public discussion of the problems of drugs of dependence in general and of cannabis in particular. One of the hallmarks of modern society is that it has found ways of bringing into intelligent discussion matters which were taboo only a few years ago. The time has now come when drug dependence, like attempted suicide, should be counted as a psychological problem and not a piece of criminality. To say this is not of course to pretend that drug dependence is a harmless condition, but simply to imply the hope that it is remediable. This is why the third urgent need is for more consistent and thorough means of treatment for those who are dependent on drugs like heroin—the scheme for setting up (in Britain) centres for the treatment of those who used to be known as addicts has been less successful than it might have been.

The most difficult problem remaining to be tackled, however, is that of knowing what should be done about the conventional opiates—alcohol and tobacco—not to mention those drugs such as barbiturates which are already so widely prescribed by doctors that many users must already be dependent on them. The first goal should be a much more consistent view of how damaging these materials may be. Is tobacco, for example, to be valued except for its side-effects? What of alcohol? Few would deny, by precept as well as words, that social drinking has some valuable, desirable or at least desired attributes. The snag is that many of the side-effects are unwelcome. So is it sensible to put alcohol on sale in the shops but to remain hard-faced about the supply of cannabis, the chief effects of which are said to have much in common with those of alcohol but which may have less damaging side-effects? This, of course, is a rhetorical question to which Mr Hogg's dictum is only partly a rhetorical answer. Among many of those who use cannabis, it is perhaps more relevant that their dispute with convention and the law seems to be a dispute between generations (which also implies, democracy being what it is, either that they have time on their side or that ageing pot-smokers can be relied on to give up the habit). But there are deep issues of principle involved in any attempt to prevent people from doing something which may not be harmful to themselves, which may not cause harm to other people and which may even be pleasurable. It will be a long time before the pot lobby has proved along these lines a case for licit cannabis, but long before then it is likely that the opiates of the middle-aged will have to be sold on licence, so many are the contradictions which have now accumulated.

Airport Outcry

ALONG with Rynemede and Crichel Down, the English name of Stansted will no doubt become one of the symbols of how sense can triumph over bumbledom. It is also well on the way to being a proof of how badly governments are advised on technical matters. The latest publication in the series put out by the Commission on the Third London Airport (*Papers and Proceedings*, Volume VII, HMSO, £4.20) is a final proof of that. Three years ago, the civil servants responsible for picking somewhere to land passenger aircraft settled on the sleepy village of Stansted in Essex because there was already a runway in operation and on a simple comparison of the capital costs of building there and elsewhere. The most immediate outcry came from those who said, quite rightly, that no attempt had been made to quantify the cost of keeping sleeping villages awake at night. The more serious indictment of the original decision was the falsity of the belief that in the planning of an important public project such as an airport, the initial capital cost is all that matters. In an ideal world, the objective should be to find a site that will maximize the benefit accruing to those who use airports and to those who never go near them. The chances are that the hidden costs are much more important than those of pouring a strip of concrete over virgin farmland.

This is what the Roskill Commission has discovered. The cost–benefit analysis now published as part of the latest instalment in the research programme shows that the cost of the airport itself—car parks and cafeterias included—works out at about £180 million for each of the four alternative sites considered in the study. (The sums of money are quite legitimately discounted to 1975.) This expenditure is entirely dwarfed by items such as "passenger user costs"—the notional but nevertheless real cost of moving people to and from the terminal buildings. For the three inland sites considered as part of the study, all of which lie north of London, surface travel of this kind is reckoned to work out at between £870 and £890 million, but the surface travel cost of the Foulness site in the Thames estuary is estimated at the equivalent of a capital sum of £1,040 million (in 1975), an understandable reflexion of the comparative remoteness of that place. In the same way, the cost of "airspace movement" is in all cases much larger than the cost of building the airport itself—the estimates range from £960 million to £990 million. One of the merits of this study is that some attempt has been made to cost the nuisance caused by noise and the disruption to various other kinds of services—agriculture and recreation at each of the four sites, for example—and nobody will be surprised that these factors go some way to compensate for the extra cost of getting people to and from the site in the Thames estuary. The result is that in terms of equivalent capital expenditure in 1975, the extra cost of the Thames estuary site at Foulness works out at £2,385 million, or something like five per cent more than the cheapest of the inland sites.

What then is the scandal? Did not the British Government always say that it would be too expensive to build the third London airport in the Thames estuary? The truth is, of course, that the basis of the analysis now being used is quite different from that on which the original decision was promulgated. Moreover, it is now apparent that the new basis is more valid than the old candle-counting procedure which the government's advisers first sought to use. Then, for example, in May 1967, the argument turned on the £15 million that would be spent on strengthening the terrain beneath the Thames estuary site then in fashion (on the south bank of the river, not the north). The result was an attempt to distinguish between the sites then available by taking account of items adding up to between five and ten per cent of the total cost of building and operating a modern airport. Three years ago, there seems to have been an almost total failure to appreciate that the third London airport would not be a simple concrete structure out in the fields or marshes but, rather, part of a closely integrated transport system which would have to be valued not in terms of how much it would cost to build but by the contribution it would make to the efficacy of air transport. And the neglect of discounted cash calculations in the original comparison is a kind of arithmetical boob for which students are now being—or should be—drummed out of first-year classes in economics. The minister who did most to defend the decision, Mr Douglas Jay, has already left the government on another issue, but nobody would pretend that he was personally responsible. The fault lies in the Civil Service, and it would help to restore public confidence if there were now some ostentatious sign that matters are being put right.

There remains the question of where the third London airport should be built. One of the most conspicuous features of the splendid study which the Roskill Commission is embarked on is that the variation from one site to another is a small percentage of the total cost. Given that the new airport must be close on fifty miles from Central London, it is inevitable that the mere cost of building the fixed installations will be a comparatively small part of the total cost. Moreover, it is clear that there are not merely considerable errors in the calculations which have been attempted but serious doubts about the basis on which some of the items in the calculation have been evaluated. Many people, for example, will say that the commission has underestimated the cost of the disturbance likely to be caused by aircraft noise. It is also possible that the comparatively high cost of surface movement to and from the Foulness site will serve as a spur for the design of better surface transport, thus helping to cancel out the present apparent disadvantage of building there. In short, the chief conclusion from the calculations so far made public is that there is very little to choose between one site and another. No doubt the Roskill Commission, in due course, will put its own gloss on the figures, and on the showing so far the result will probably be convincing. But it is only prudent at this early stage to acknowledge that the numerical comparison of the several sites available is likely, if taken seriously, to underline the importance of those considerations which cannot be quantified and which have not been fully counted in the calculations. In short, the airport will be best placed where it will be the least nuisance. Foulness, it would seem, is the best place.

Science Policy now Respectable

It has been announced that Mr Christopher Freeman, director of the Science Policy Research Unit at the University of Sussex, has been elected to the first university chair ever created specifically for science policy. The new chair has come as part of the requests made last November by Reginald M. Phillips of Brighton for science policy research at Sussex. The precedent will be of interest to all who have seen in the social studies of science an emerging field of activity, capable of pooling the talents and resources of many traditional disciplines. Coming at the end of a decade that has seen increased systematic academic and governmental interest in the relations between science, technology, economics and cultural development, this event augurs well for the field's future in this country.

As director of the SPRU since its creation in 1966, Christopher Freeman deserves much of the credit in science policy at Sussex. Previously he had pioneered the use of international statistical comparisons of research and development that have since become everyday instruments in governmental and intergovernmental decisions. Born in 1921, Freeman graduated with first class honours in economics from the London School of Economics in 1948. In 1959 he joined the staff of the National Institute of Economic and Social Research and shortly thereafter became involved in work in the OECD on international comparisons of research and development. This included preparation of a manual of proposed standard practices for surveys on R&D for the Frascati Conference on this subject in 1963. At the NIESR Freeman led research into the electronics, plastics and chemical process plant industries, and became a frequent consultant in Europe on questions concerning the economics of science. In 1965 he was invited by the University of Sussex to create the first British university centre in the science policy field.

Under Freeman's leadership and largely in response to requests from government and industry, the original group has grown in four years from two to over thirty research fellows, research students and staff. Its activities range from social and economic history of science to the relationship between science, industry and economic development, both in advanced and developing countries. Within the last two years fresh work has begun on the study of science in China and the Far East, on the economics of innovation and on safety in industry. Teaching duties of the unit's staff bring it into close contact with both science and arts schools of the university, while its research has made it a focus of international interest. Although the Phillips chair does not attempt to answer the unit's need for long term continuing support, it is a welcome witness to the increasing significances of science policy studies, which Christopher Freeman has helped to pioneer.

100 Years Ago

We referred last week to the "situation" at the Paris Observatory. The action of the French Government has been of the promptest and M. Le Verrier is no longer Director. This step indicates very clearly—too clearly we fear—the strength of the case put before the Minister of Public Instruction, in the memorial, of which a copy has been sent to us. This document, which is signed by all the *chefs de service*—Villarceau, Marié-Davy, Wolf, and Loewy—and the *astronomes adjoints* without exception, discusses all points connected with the administration of the Observatory, scientific and otherwise. It is to be sincerely hoped that M. Le Verrier may be able yet to do service to astronomy, in some other capacity, some position where his great talents alone will be called into play. His is a name that will never die, let us hope it is but momentarily eclipsed.

From Nature, **1**, 387, *February* 10, 1870. *The "situation" referred to was that the entire staff of the observatory had threatened to resign if Le Verrier were not dismissed, because of his uncompromising policies. He was reinstated at the observatory in* 1872, *but with reduced powers.* Nature's *comment on February* 3 *was that "the present régime at the Observatory of Paris has been rather more autocratic than could be patiently endured, even in a country subjected to eighteen years of personal government". Le Verrier predicted the existence of Neptune in* 1846, *without knowing that Adams had reached the same conclusion in England.*

UNIVERSITY ENTRANCE

Continuing the Swing

by our Education Correspondent

More than 1,300 places in the science, engineering and technology faculties of British universities were unfilled last October. In May 1969 the universities estimated that 10,447 engineering and technology places and 16,828 science places would be available this year. But in the event, only 9,984 and 15,978 students were admitted to these faculties, representing a shortfall of 463 and 850 respectively. This reduction in numbers, given in the report of the Universities Central Council on Admissions for 1968–69, seems to have been caused by a lack of suitably qualified applicants. In the sciences, the number of applicants was only 1·5 times greater than the number of places available, while the ratio for the arts was 1·8 : 1 and for the social sciences it was 2·5 : 1.

Because of the lack of competition for places, science, engineering and technology faculties seem to be willing to accept students with significantly lower qualifications than those accepted by arts or social science faculties. During the clearing procedure in September, when unfilled places are filled by suitably qualified candidates who were unsuccessful in the first round of the lottery, 38·5 per cent of the engineering and technology candidates and 37·4 per cent of the science candidates were accepted, compared with 14·9 per cent of the social science and 21·0 per cent of the arts candidates. Moreover, if A-level grades are awarded points—five for an A grade down to one for an E—282 candidates out of 922 with scores of five or less were awarded places in mechanical, electrical and civil engineering in the clearing procedure, compared with thirteen out of 343 in English.

The total number of admissions, at 61,139, was 3·1 per cent up on the total for October 1968, however, but the report says that "if suitably qualified candidates had applied in sufficient numbers, the increase in admissions could have approximated to 4·5 per cent". The number of applicants for university places was 114,289, which suggests that there are almost twice as many candidates as there are places available. But Dr Geoffrey Templeman, chairman of UCCA, suggests that this is misleading. He says in the introduction to the report that about one in five applicants do not achieve the minimum university entrance qualification, and that about 15 per cent of those who apply in any given year can be expected to have applied for admission in a previous year. He suggests, therefore, that about three out of every four qualified candidates were awarded places last October.

GRADUATE EMPLOYMENT

Industry's Share Growing

Graduates who go straight into employment in Britain now outnumber those who continue to study. The University Grants Committee's latest volume of statistics (*First Employment of University Graduates, 1967–68*, HMSO, 10*s*) shows that out of a total for the year of 42,615 graduates with first degrees, 17,508 took up a job in Britain and 17,047 carried on with their education. In 1966–67 the figures were 14,775 and 15,190 respectively. Industry seems at last to have reversed its declining attractiveness to graduates,

Table 1. DISTRIBUTION OF FIRST DEGREE GRADUATES BETWEEN EMPLOYMENT AND FURTHER EDUCATION

Percentages in:	1965–66	1966–67	1967–68
Further education	41·7	41·6	40·0
UK industry	25·1	25·1	25·7
Other UK employment	14·9	15·3	15·4
Others (including emigrants)	18·3	18·0	18·9

Table 2. EMIGRATION OF GRADUATES

First degrees	1965–66 (per cent)	1966–67 (per cent)	1967–68 (per cent)
Total emigrants	6·1	5·2	4·9
Pure scientists	4·3	3·7	3·8
Applied scientists	6·1	5·7	5·1
Permanent emigrants	1·6	1·4	1·2
Pure scientists	1·3	1·0	0·9
Applied scientists	3·4	3·1	2·6

Higher degrees	1965–66 (per cent)	1966–67 (per cent)	1967–68 (per cent)
Total emigrants	14·2	13·8	13·3
Pure scientists	19·5	19·1	18·0
Applied scientists	10·9	11·8	9·8
Permanent emigrants	6·7	6·9	6·2
Pure scientists	6·7	7·0	6·5
Applied scientists	8·6	9·5	6·8

"Total emigrants" and "permanent emigrants" are shown as percentage of the total number of graduates (42,615 for first degrees; 9,135 for higher degrees). "Pure scientists" as percentage of pure science graduates (12,993 for first degrees; 3,931 for higher degrees). "Applied scientists" as percentage of applied science graduates (8,198 for first degrees; 2,280 for higher degrees).

Permanent emigrants are "those who may reasonably be assumed to be lost to the British market at least for some years".

for its share rose from 25·1 to 25·7 per cent of the year's output (see Table 1). More encouraging still is a continuing fall in the proportion of emigrants—the figure of 4·9 per cent compares with 5·2 per cent for 1966–67 and 6·1 per cent for 1965–66.

The total number of first degree graduates includes 30,151 men and 12,464 women, and compares with the previous year's total of 36,528. Apart from the reversal of the trend away from industry, however, there has been little change in graduate career patterns. Teaching, for example, is still losing its popularity—the proportion that entered directly fell from 13·9 to 13·3 per cent of those taking up employment. The proportion that went into teacher training was unchanged.

A further 9,135 people graduated with higher degrees, comprising 8,150 men and 985 women and topping the numbers for 1966–67 by 1,758. Here, too, more have been looking to industry for a career—12·7 per cent in comparison with 11·8 per cent for 1966–67. The fall in the proportion of PhDs among the higher degrees awarded—from 61·4 per cent in 1963–64 to 47·4 per cent in 1966–67—has, however, been checked. In spite of the Swann report's recommendation that shorter periods of postgraduate study should be encouraged, the 1967–68 figure for PhDs was reduced only to 45·7 per cent.

With a little further analysis, the UGC's statistics reveal that between 1965 and 1968 the brain drain among newly graduated people was, in relative terms, significantly reduced, even though the numbers of emigrants continue to increase. Table 2 shows that 1·2 per cent of first degree graduates and 6·2 per cent of higher degree graduates went abroad "permanently" (the UGC's term for an indefinite length of time) in 1967–68. Two years earlier, the respective figures were 1·6 and 6·7 per cent. The fall for the total of emigrants is more marked. Although the extra graduates that the totals include intended to return to Britain after a period of overseas work or study, the experience of their predecessors suggests that they may not be able to find jobs when they want to come back (see *Nature*, **225**, 213). The net loss is thus likely to be somewhere between the two extremes that are given in Table 2.

Two features here call for further comment. First, perhaps surprisingly, relatively few pure scientists with first degrees go abroad—a total of 3·8 per cent in 1967–68, compared with 4·9 per cent as the proportion of all graduates. Against this, however, should be set the fact that 25·5 per cent of pure scientists continued academic study or went into research, compared with 18·6 per cent of all graduates. Second, applied scientists are more likely to go abroad permanently than pure scientists. While 18 per cent of pure scientists with higher degrees emigrated, only 6·5 per cent intended to stay abroad; among applied scientists, 9·8 per cent emigrated but the departure was permanent for 6·8 per cent.

Mr Enoch Powell has given widespread publicity to a survey by the Cambridge University Management Group, which reported that 27 per cent of an undergraduate sample were considering permanent emigration. Even allowing for subsequent emigration by some of those who start work in Britain, the UGC's figures suggest that many of the interviewees will have had second thoughts by the time they graduate.

TELEVISION BROADCASTING

Cable Talk

It is one thing to show, as Rediffusion's laboratories have in Britain, how cables can bring many more television channels into the home than can aerials on the roof. It is something else again to work out how cable television is to co-exist with conventional television broadcasting. In the United States, the broadcasting industry regards cable television as the dog in the manger. It steals programmes out of the air without paying for them, and transmits them to subscribers for a fee. And it threatens to grow into a national network, local cable companies joining up and perhaps receiving their signals from satellites, bypassing the conventional broadcasting networks altogether.

A report released last week by the Rand Corporation suggests how cable television might be encouraged to grow without running wild. Cable operators should be allowed to carry whatever programmes from whatever distance they choose (the Federal Communications Commission now places severe restrictions on their freedom to import signals), but they should pay for what they take. They should be allowed to originate programmes themselves (the first real hope that something like local television will ever come to pass) and they should be allowed to sell advertising—at least to pay for the programmes that they prepare themselves—and they should be allowed to interconnect into regional and national cable networks.

There is a threat in all this, in spite of the diversity implicit in the provision of 40 or 100 television channels to every television set, instead of two or three. The entire flow of information into the home would then be in the hands of a single operator. The best way round this, the Rand study suggests, is for certain channels to be given the status of "common carriers"—television service to be for sale to the public, just as telephone service is. The American Civil Liberties Union, incidentally, has also put its weight behind this idea.

All very well for the cable companies (who are having no trouble finding people willing to invest their money in what they see as tomorrow's goldmines), but what about protection of the broadcasters ? What they do offer is television, or radio, programmes free to the public. Cable companies charge a fee (about $5 a month in the United States) for wiring a home for television; people are willing to pay this because of the better reception or the increased choice of programme involved, but obviously there are many who, having scraped together the money for the set, could not afford the further cost. The Rand report concludes, perhaps too optimistically, that as long as cable television operators pay broadcasting stations for the signals that they take from the air, the broadcasters should find that what they lose in advertising revenue they would gain, roughly speaking, in royalties. The Rand theory is that just as radio broadcast has continued to grow in the face of competition from television, broadcast television should grow in spite of, or perhaps even because of, cable television. If legal restrictions were necessary, these might take the form of giving the broadcaster an exclusive period of time during which the cable operators might not show his programme.

Cable television has grown enormously in the United States, where it accounts for about six per cent of all the television reception. Its most spectacular growth, however, has been in Canada, where it is popular because of its ability to bring the signals of American broadcasting stations. Montreal has the largest concentration of cable television subscribers (100,000) in the world. In Britain, Rediffusion Ltd has just unveiled a system which could distribute twenty television programmes to entire towns or to a large housing estate and, moreover, is capable of being two-way; programmes could be injected from any part of the network.

PARKINSONISM

Scowen Committee Defied

The British company that intends to sell the scarce drug L-dopa, used for treating Parkinson's disease without submitting it to the Scowen Committee on the Safety of Drugs, has receive a sharp reproof from the Department of Health and Social Security. Mr Malcolm Sinclair, director of Chemica Laboratories Ltd, said last week that although he had offered the committee samples of his product, he was not prepared to divulge his manufacturing secrets. Because he felt unable to withhold his supplies from the home market any longer, he would by-pass the committee. The Department of Health, on behalf of the committee, quickly retorted that Chemica had ignored advice given to its representative last October, and had provided none of the required information about its preparation of L-dopa. Manufacturing procedures, the department points out, are treated in strict confidence, and no problem has arisen in dealing with nearly 600 other organizations.

The drug at the centre of this argument was first investigated as a possible cure for Parkinsonism after the discovery that drugs which cause a decrease in amounts of monoamines, particularly dopamine, in the brain can cause the disease (*Nature*, **223**, 889; 1969). Trials so far have shown that the L-form of this amine can relieve the symptoms—including rigid limbs and trembling hands and legs—in some but not all sufferers. It may also have side effects such as nausea and lowering of the blood pressure. In trials in the United States some patients suffered such ill effects that treatment had to stop. Only 5 per cent of patients experienced a real cure, although another 55 per cent were partly improved.

In Britain the very short supplies of L-dopa have been restricted to MRC clinical trials on the decision of the Department of Health. Until last week the only preparation passed by the Scowen committee for use in the trials was made by Roche in Switzerland. But now two more firms, whose names have not been revealed, have received clearance for clinical studies of their preparations in the treatment of Parkinsonism.

This should help to ease the shortage of supplies, which Mr Sinclair of Chemica says is one reason why he is going to sell his unscreened preparation in Britain. For fourteen months, he says, his company withheld supplies for ethical reasons, only to find that its exports were being imported back to Britain and sold at exorbitant prices. This, combined with the pressure of enquiries from doctors and patients, has given Chemica no choice but to sell its preparation direct to British doctors, who are, of course, free to prescribe the drug if they consider that it will benefit their patients.

Submission of drugs to the Scowen committee is at present entirely voluntary. A company wishing to market a drug approaches the committee with details of the preparation and trials carried out. If the committee is satisfied with the evidence, the drug is passed for sale; this apparently simple procedure is common with many of the preparations submitted. In the case of L-dopa, clearance has been restricted to the clinical trials, which are not expected to be completed for some months. Some people have been feeling impatient with the committee's slowness in making more supplies available. Among them is the Parkinson's Disease Society, which has been urging the Department of Health to improve the situation. Founded a year ago, the society is principally concerned with the social welfare of sufferers, but has made its voice felt on the question of L-dopa, which it believes to be a useful treatment, but not a cure. Although anxious to see more supplies made available, the society cannot support Chemica in flouting the Scowen committee.

ENRICHED URANIUM

Questions from Europe

When the news that the terms of the centrifuge agreement had been approved by Britain, the Netherlands and West Germany was announced just before Christmas, after long and hard negotiations, the Ministry of Technology made light of the condition that the agreement also had to be submitted to the European Commission for approval. It must have seemed that the commission was hardly likely to object, with the European Community's nuclear club—Euratom—still in something of a parlous state despite recent lifesaving efforts. It now seems that the ministry was over-optimistic about what seemed to be a formality.

Both the Netherlands and West Germany are members of Euratom, and under Article 103 of the Euratom treaty a member state has to submit draft agreements involving non-Euratom organizations to the European Commission. If the agreement contains clauses which go against the Euratom treaty, the commission has to communicate its observations to the Euratom states concerned within a month. This seems to be what has now happened. Although there is no official news of what the objections are, one possibility is that the commission is worried that Britain would be able to prevent members of the Community not in the centrifuge collaboration from access to the uranium. Under the draft agreement there is to be a joint committee with members from Britain, the Netherlands and West Germany to deal with relationships with other states, but the commission must feel that this is not enough to safeguard the interests of the Community as a whole.

The point of the centrifuge method is that it ought to be possible to produce enriched uranium at a price comparable with what the US Atomic Energy Commission charges—$26 per kg of separative work. Precisely what the selling price is likely to be has not been made known, and all that Mr Benn will say is that it will be competitive with the American product. At present, all the members of the European Community are supplied from the United States, with the exception of France which operates a gaseous diffusion plant. Part of the trouble seems to be that the Community is at present discussing arrangements for the supply of enriched uranium in the future and is bound to be disturbed with a *fait accompli* by two of its members.

Although the centrifuge has small beginnings—an aim of 50 tonnes of separative work in 1972—what the collaboration is working towards is the 15,000 tonnes which is the predicted European requirement by 1980. With this target in view, the commission is hardly likely to torpedo the project once there is assurance that it can be integrated into a European framework, and the Belgians and Italians have already been interested in joining. Once again, like the agreement to rescue Euratom early in December (see *Nature*, **224**, 1047; 1969), the move is as likely as not a political decision, and is another indication that Europe's nuclear policy is hardly likely to be settled until the question of British entry to the Community is decided one way or the other.

CERN ACCELERATOR

When is the Last Bus?

PROSPECTS for the proposed 300 GeV CERN accelerator are starting to look rather bleak. The West German Government finally called off the ministerial meeting scheduled to be held in Geneva last week after a period of tough talking between the German and Belgian Governments over the siting of the accelerator. Little progress seems to have been made in quelling the West German Government's conviction that it should now put pressure on its European partners for a fairer deal in joint scientific ventures, and there seems little chance that any of the other five participants to the project will allow the siting of the project to be determined by anything resembling strong-arm tactics.

One theory, which has made its way into print in the Belgian newspaper *Le Soir*, is that the West German Government has been re-evaluating the project and has found it too expensive. This would explain the odd timing of the announcement that the Federal Government will reconsider its participation if the West German site near Munster was not selected at the December meeting of the CERN Council. Some doubts have, in any case, been expressed about the suitability of the German site. Another view is that the French Government has decided to back the Belgian site in return for the purchase of Mirage aircraft by the Belgian Government, but in such a fluid situation the wildest speculations can easily gain a hold.

In one sense the British Government's decision to steer clear of the project may be held as the primary cause of the impasse, placing a heavier financial burden on each of the other governments and so elevating the importance of the location. In another sense, however, British participation would have added another arm to the multilateral tug of war, and the British Government may be feeling that it made the best decision after all.

FABIAN SOCIETY

Priorities in Education

by our Education Correspondent

THE Department of Education and Science should publish a green paper to stimulate discussion about the possibilities that exist at every level of education and their financial consequences. This, according to a pamphlet published by the Fabian Society, would provide a basis for informed discussion about priorities in education, and would help in the formulation of a national plan on the subject. The authors of the pamphlet strongly criticize the British Government for attacking the problem of expansion in education on a piecemeal basis and, in turn, they call for rapid expansion of nursery education and for more provision for further education of students leaving school at the age of sixteen.

The pamphlet is a brave attempt to assess priorities in education, and it also attempts to calculate the costs of alternative policies. The authors argue that if existing policies are continued, the share of the gross national product devoted to education will grow from the present 5·7 per cent to about 8 per cent in 1980, but if the policies that they recommend are adopted, then the figure would be about 9 per cent. This estimate is based on proposals for universal nursery education, the employment of teachers' aides in primary schools, as suggested in the Plowden Report, fully comprehensive education in secondary schools, a major expansion of further education and reorganization of higher education.

As far as higher education is concerned, the authors of the pamphlet argue that the Robbins committee grossly underestimated the likely demand for higher education. The major problem, they argue, is to increase the number of students and still maintain the existing standards of building and the staff/student ratio. The pamphlet calls for a greater variety of full and part time courses in the universities, and suggests that the main developments of this kind are at present occurring in the polytechnics. Boosting the polytechnics is therefore right in the short term, but "over a period of time, the separation of institutions of higher education into distinct classes could have most undesirable results". The authors argue that because the polytechnics devote a lower proportion of their resources to research, they offer fewer senior posts, and that the facilities provided for their students are inferior to those provided by the universities. If this situation persists, polytechnics will be nothing more than second class institutions, and the part they play will be devalued with them. The authors of the pamphlet therefore believe that "in due course federal structures should be developed, each of which should embrace all the institutions of higher education within its area".

The authors of the pamphlet were Professor H. D. Hughes, principal of Ruskin College, Oxford, Caroline Benn, editor of *Comprehensive Education*, Tessa Blackstone, David Downes and Howard Glennerster, lecturers at the London School of Economics, and Stephen Hatch from Brunel University.

LONDON UNIVERSITY

Taking the Strain

by our Education Correspondent

If the latest projections of student numbers in 1980 prove to be correct, the University of London external degree system will break down. The government and administration of the university will also be severely strained. These fears have prompted the setting up of a joint committee of the university and the Universities Grants Committee to look at the future of the University of London as a federal institution. The committee of inquiry will have sweeping terms of reference, but it will concentrate mainly on the organs of government of the university—the Senate and its standing committees, the convocation and the court—and it will also consider how staff and students can participate in the decision-making process.

The university Senate said last week that since 1962 its policy has been not to increase its external examining commitments, but despite the advent of the Council for National Academic Awards, the number of external degree students has increased by almost 50 per cent during the last eight years, and the external examining resources of the university are already severely strained. The committee of enquiry will therefore look at the relationship between the internal and external degree systems.

Such a committee is not without precedent. In 1963, the Robbins Committee said that the University of London has problems which call for investigation and remedy, and, if those problems could not be resolved internally, they "should be the subject of independent inquiry". The university set up a steering committee to consider the implications of the report, and since then, the Senate says, the academic organization of the university has been completely reshaped. But there are still problems which require outside help, and the University Grants Committee has agreed to cooperate in establishing the committee of inquiry.

WOLFSON FOUNDATION

More Grants to Universities

The Wolfson Foundation is to make further grants for university research projects likely to benefit British industry. In November 1968, the foundation supported fifteen projects to the tune of about £1 million (*Nature*, **220**, 1165; December 21, 1968) and General A. R. Leakey, the foundation's director, has indicated that a similar sum may be made available at the end of this year. The total value of the grants will, however, depend on the applications received from the universities.

The foundation's last spending spree in the universities attracted more than 150 applicants, and the fifteen chosen for support make an impressive list. It seems that the Wolfson Foundation has not found itself inundated with applications which have been turned down by other grant awarding bodies and, indeed, many academics may even apply to the foundation in preference to the research councils because it places less restriction on the way the grant is spent. Among the projects already being supported are several liaison units between university and industry. For example, the Wolfson Microelectronics Liaison Unit at Edinburgh, the Wolfson Industrial Unit at Southampton and the Wolfson Bioanalytical Centre at the University of Surrey are all hoping to undertake direct consultancy work for industry, the intention being to earn money for research which may have immediate industrial application. Other projects chosen for support also have potential industrial applications; for example, Birmingham is developing a high-speed press driven by combustion of hydrocarbon fuels and the University of Wales Institute of Science and Technology is setting up a centre for the technology of soft magnetic materials. Grants which will be awarded this year will probably support similar projects, and applications must be made before July.

INFRARED ASTRONOMY

Latest Light Bucket Ready

by our Astronomy Correspondent

One problem facing Professor Jim Ring this week has been how to get a 40-inch infrared telescope out of the cellar of 10 Prince's Gardens, the terrace-house home of the infrared astronomy group at Imperial College, London. The telescope is the latest step in a progression which people are hoping will lead one day to the building of a 120-inch infrared telescope for the consortium of British universities which have banded together to promote infrared astronomy. But the 40-inch telescope is an Imperial College venture, built on a shoe-string budget of £2,500 and started before the Science Research Council a year ago announced the award of £27,000 to the Imperial College group. This grant is earmarked for a 60-inch telescope, the next step in the path to the 120-inch, now past the design stage and awaiting detailed drawings before the parts go out to tender in April or May.

Infrared telescopes, more properly called flux collectors—light buckets in the language of astronomy—are cheap compared with similar equipment for the visible spectrum because the optics do not have to be so accurate. This leaves the way open for unusual optical systems, and the 40-inch has a novel design even for infrared telescopes. Light is directed on to the 40-inch paraboloid by a glass flat about 60 inches across. Because of the problem of supporting a sheet of glass this size, the flat is made up of a circle of six hexagons with a hole where the seventh hexagon in the pattern ought to be. The paraboloid converges the beam to a focus through the hole, and this is where the detectors will be fixed.

The next step is to transfer the telescope from the basement workshop at Prince's Gardens, where it was built because of problems of space and floor strength, to the Imperial College out-station at Silwood Park, Ascot. Here it will be used chiefly to test infrared systems, but Professor Ring hopes it will be possible to do some real astronomy through the moist air of Ascot. Although the important wavelengths at 10 microns are badly affected by water vapour, the band at 1 to 3 microns ought to be clearer and Professor Ring wants to record the infrared emission from the Orion Nebula. To get it out of the cellar, the telescope will probably have to be broken down into three components, and the Imperial College group is happy that the transfer will be accomplished safely.

Meanwhile the search for a permanent site for the 60-inch flux collector with the requisite minute amount of water vapour in the atmosphere has narrowed down to the Sierra Nevada Mountains in Spain and, rather pleasantly, Tenerife in the Canaries, where an inversion makes the atmosphere drier than expected for an island site. Testing is to go on at both places for most of the year, when the decision on the site should coincide with the completion of the 60-inch telescope expected by the end of this year. The mirror blank is at present being polished at Grubb Parsons optical works. Compared with an image size of 30″ of arc for the 40-inch telescope, the 60-inch telescope is expected to produce an image of 1″ of arc or so.

What form the 120-inch flux collector is to take—if it is built—is still under discussion, and much revolves around what wavelengths people most want to observe. One school of thought favours adding to the world's arsenal of 60-inch flux collectors before going to bigger instruments. These are questions which will have to be discussed before the British family of flux collectors grows further.

INSTRUMENTS

Microscopic Microanalysis

A POWERFUL new instrument which combines the facilities of an electron microscope and an X-ray microanalyser has been jointly developed by Tube Investment Research Laboratories near Cambridge and AEI Instruments at Harlow. The electron microscope microanalyser (EMMA) can simultaneously magnify and make an X-ray analysis of minute areas of material one tenth the diameter of the smallest objects visible in conventional electron microscopes. There are likely to be many uses for the instrument both in metallurgy, for which it was originally designed, and in biological and pollution research.

The advance which made EMMA possible was the invention of a miniature focusing lens to replace the bulky lens usually used in electron microscopes. The lens allows X-rays emitted at the surface of the specimen to be analysed by a series of spectrometers without interference from the lens. By removing the need to transfer a specimen constantly between a microanalyser and a microscope the new instrument makes possible precise analyses of small regions of the sample which are inaccessible by techniques involving two instruments. The electron beam in EMMA can be focused down to a diameter of about 1000 Å, and samples, which are in the form of thin films, can be magnified up to 160,000 times with a resolution of about 10 Å. The electron microscope is designed to operate at up to 100 keV, and in this range all elements with atomic number greater than about ten can be picked out by the spectrometers.

An interesting series of trials have already been carried out with EMMA. Surface cracks on steel tubing have been analysed and shown to contain particles of aluminium nitride with a diameter of 1500 Å, well below that resolvable in a conventional electron microscope. Certain steels are known to owe their creep resisting properties to plates in the structure, commonly thought to be silicon nitride. Analysis with EMMA revealed that some of the silicon sites were in fact occupied by manganese atoms, the presence of which had been concealed in the simple diffraction pattern.

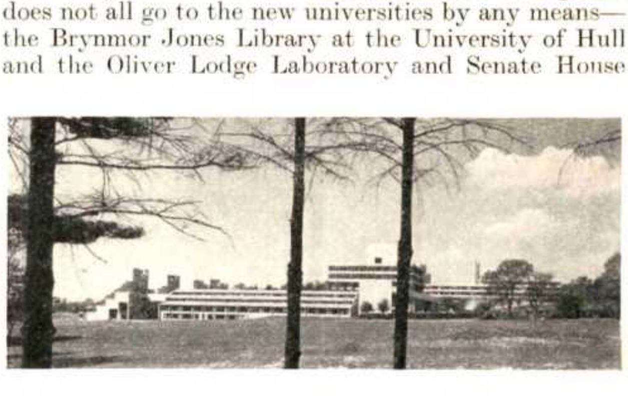
Asbestos fibres extracted from a human lung have been identified in EMMA as coming from a particular asbestos known as Amosite. By studying these fibres, which are often only 1000 Å thick, it may be possible to find out more about the disease known as asbestosis. In another test, the eyebrow of a chick has been studied. The cells were found to contain more phosphorus and less calcium than did the extra-cellular space, in which there was an excess of calcium. Dust particles collected in the upper atmosphere by an American rocket have also been analysed, and the absence of nickel has precluded the possibility of their being micrometeorites. The tests suggested that the particles probably came from a steel works in Sweden, showing the great potential of the instrument for studying problems associated with pollution.

Sales for the new instrument, which will cost between £35,000 and £45,000, are likely to be at least fifty a year according to AEI. The chief sales problem is expected to be in making people aware of the range of research tasks that can be undertaken with the instrument.

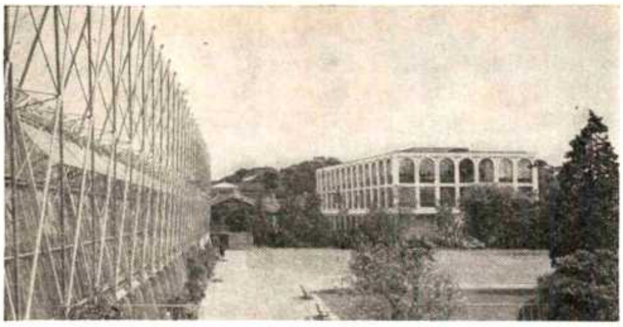
ARCHITECTURE

Prize Universities

THE encouragement given by British universities to good architecture in the past few years is reflected once again in the new crop of Civic Trust Awards. Among the 198 schemes for new buildings, restorations or landscape projects that have been recognized by the trust for the top accolade, an award or for a commendation are twenty-six from universities. The trust says that the challenge of the pace of building programmes to meet the huge expansion in university expansion in the past ten years has been met "dramatically" by the university administrators and academics. Its praise does not all go to the new universities by any means—the Brynmor Jones Library at the University of Hull and the Oliver Lodge Laboratory and Senate House



University of East Anglia.



Exhibition Plant Houses, Royal Botanic Garden, Edinburgh.

at the University of Liverpool (see *Nature*, **222**, 613; 1969) each receive one of the new awards.

On the new universities, the trust describes the designs for the University of East Anglia as the "boldest" of the master plans for the twenty-two new universities established in the past ten years. The first stage, which has been designed by Denys Lasdun and Partners, is set on the south-facing slopes of an open valley. Much of the credit for the high standard of university building, the trust says, is "due to the enlightened commissions" from the universities. "Why," it asks, "should not every government department and nationalized industry be given an equal lead in every new building for which they are responsible?" This is not to say that government departments do not win awards from time to time—indeed, the trust notes one or two schemes in the latest batch of awards—but, compared with the universities and with office buildings, government sponsored building is, as the trust says, not impressive. One that has made the grade is the Exhibition Plant Houses which have been built by the Ministry of Public Building and Works for the Royal Botanic Garden in Edinburgh. The buildings, which house subtropical and tropical plants, have supporting structures outside the glazing to protect them from the corrosive conditions normally found in plant houses. The assessor describes them as fitting in admirably with the adjacent herbarium (itself an award winner in 1966) and with their long horizontal lines and delicate and decorative pattern of external framing, they are "both gay and formal, an entirely appropriate character for their environment and one very difficult to achieve".

CONSERVATION

Italy's Obscene Harvest

The Italian Government has ushered in what was to be known as European Conservation Year with a measure that could be described as inauspicious. It has passed a bill which permits the netting of small birds, a practice which was banned in most of its aspects three years ago, as a result of which some 10 million migrants crossing between Africa and northern Europe are expected to perish each season, beginning from this autumn.

The bill, which has been passed on the initiative of the Italian Minister of Agriculture and Forests, and with the zealous support of the Under-secretary at the ministry, Signor Arnaldo Coleselli, is said to be necessary because the 1967 law impeded the capture of birds for scientific research. This has been denied by the Italian National Research Council.

An article in the Milan newspaper *Corriere della Sera* refers to the bird netting as an "obscene harvest" which will lose Italy friends abroad and even engender enough resentment to harm the tourist trade. Italy is the only European country in which small birds are netted for sport and eaten. A bill passed in 1967 which forbade the shooting of birds was intended to be the first step towards the total abolition of bird hunting. But the Ministry of Agriculture has now put the clock back against the appeals of the National Research Council and the protests of conservation societies.

ENGINEERING

Mr Howden's Ingenious Machine

An engine that can convert the thermal expansion of solids or liquids into useful mechanical work seems, on the face of it, not to be the most workable of ideas. Mr Patrick Howden thinks otherwise. He has not only developed his thoughts far enough to get several universities interested, but has built a working model to prove his point. Although what has emerged so far is clearly primitive, Mr Howden—a London physicist—claims that his engine promises in theory to be more efficient than the internal combustion engine.

In its simplest form, the Howden engine consists of two long metal tubes forming an elongated V shape and mounted on a common pivot. One is heated while the other is cooled—in the model this is done by passing hot and cold water through the tubes—and the effect of the expansion is to move the base of the V horizontally. The cycle is completed by cooling the first tube and heating the second, whereupon the base moves in the opposite direction. A ratchet converts the oscillations into continuous rotation. In a televised demonstration this set-up achieved a speed of one third of a cycle per second, but six cycles per second are apparently feasible.

The difficulties to be overcome are both theoretical and mechanical. The industrial development unit at the University College of North Wales, Bangor, has performed a thermodynamic analysis which reveals that, to obtain an efficiency of 50 per cent, pressures of a million atmospheres would be required within the expanding metals. In spite of this result the unit is continuing to investigate the engine's possibilities, for it may be that given the basic idea someone will be able to envisage a more practical way of applying it. Mr Howden, undeterred, has higher hopes for a version that would use a liquid of large expansion coefficient as its working substance instead of a metal; and obviously higher temperatures would be needed than can be attained with water.

On the practical side, the present form of the Howden engine makes heavy demands on the metal from which the expansion element is made. The model uses aluminium, but the desired combination of a large coefficient of expansion with high thermal conductivity might lead to a search for new materials if the engine is ever developed. Its advantages would include cheapness and reliability, and it could run on absolutely any fuel. But at the moment the Bangor unit finds that the problems arising from theoretical work on the engine are somewhat discouraging.

Parliament in Britain

CEGB. Generating Capacity

THE Central Electricity Generating Board estimates that this year it will spend about £850,000 on research connected with 500 MW generating units, and about £1 million next year. The work will be concentrated primarily on turbines, alternators, lubrication and bearings. This information was given by Dr Ernest A. Davies, joint Parliamentary Secretary to the Ministry of Technology.

Earlier, a number of questions about the CEGB's lack of spare capacity in the event of severe demand were addressed to the Minister of Technology. Mr Wedgwood Benn stated that apart from voltage reductions amounting to between 3 and 6 per cent for eleven days in November, the board has been able to meet demand. He said that faults in the 500 MW generator sets were responsible for the lack of spare capacity, but he gave no undertaking that the board would be able to meet demand during another cold spell, or when the sets would be back in service. Sir John Eden suggested that perhaps the CEGB should have decided on a more flexible plant mix, and Mr Eric Lubbock suggested that at least some of the criticism should be directed at private industry which supplied the faulty equipment. Mr Benn would not comment on the technical aspects of the failures, however, and he did not want to emphasize the part played by private industry because of the effect such a criticism may have on British exports. (Oral answers, January 26.)

Teacher Training Grants

MR TAM DALYELL asked the Secretary of State for Education and Science what consideration he is giving to the recommendation of the report of the working party of the Royal Society that graduates taking teacher training courses should receive postgraduate grants. Mr Gerald Fowler said, however, that grant arrangements for graduates training as teachers apply to graduates training for a number of other professions, and that he could not consider implementing the working party's recommendation without taking into account many other deserving claims on the funds available for student support. (Written answers, January 29.)

Experiments on Animals

LORD SILKIN called on the Government to introduce legislation to implement the Littlewood Report on experiments on animals, and to control the export of animals for research. No legislation has been made on this subject since 1876, he said, and the Littlewood Report was completed five years ago. Lord Platt said that although he does not like experiments on live animals, they are necessary for medical research, and that people who call for a complete end to animal experiments should refuse to take antibiotics, insulin, hormones and treatment of that kind. Replying to the debate, Baroness Llewelyn-Davies of Hastoe said that, by law, drugs must be tested on animals before they are marketed, and that if international exchange in special animal strains were restricted, the chances of another disaster on the scale of the thalidomide tragedy could occur. The welfare of animals is safeguarded under the act of 1876, she said, and the government sees no reason for giving new legislation a high priority. (Debate, Lords, January 27.)

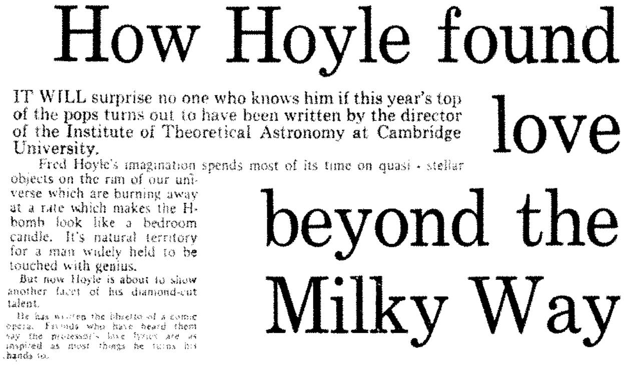
Miscellaneous Intelligence

RUMOURS that the Committee on Safety of Drugs is to recommend the withdrawal of king size cigarettes must be firmly stubbed out. The committee considers that cigarettes do not fall within its purlieu because they are not therapeutic agents and, unlike contraceptive pills, they are not "a drug administered for the modification of a physiological function". Those naive enough to think the committee is shirking its responsibilities should realize that more fundamental differences underlie this useful distinction between cigarettes and the pill. To start with, the Exchequer's revenue from cigarette duty this year was £980 million, whereas the pill is not taxed. Moreover, the pill undermines the social fabric by encouraging the sexual independence of women whereas tobacco is a social stimulant hallowed by tradition. It is true that 25,952 people in Britain died of lung cancer in 1968, compared with possibly 50 or so from thromboembolism associated with the pill, but that is no concern of the committee because nicotine is not a drug, or if it is, it is not administered to modify a physiological function, and if smokers think otherwise they must be deluding themselves.

THE discrepant estimates of the world's wild tiger population that were provoked by the recent arrival in London of Miss Gina Lollobrigida and her tiger skin maxi-coat (*Nature*, **225**, 215; 1970)—the World Wildlife Fund claimed 600 tigers and the Fauna Preservation Society 2,500—are believed to owe their difference to the old safari saying that for every tiger you see, five tigers see you.

THE United States is well on the way to becoming a Grove of Academe. In 1969, 61·4 million people, about 31 per cent of the population, were either teachers or students. Needless to say, production on this scale leads to an occasional glut; at the annual meeting of the American Physical Society in Chicago last month, only 100 employers arrived to interview some 1,500 applicants with doctoral degrees in physics.

A cow is a cow is a one-bar fire and a desalination machine; according to a handout from the Ministry of Agriculture, twenty cows give off the equivalent of 20 kilowatts of heat an hour, which equals the output of 20 one-bar electric fires. In the same interval the twenty bovids perspire 10 pints of moisture between them. Why the ministry does its sums in scores of cows instead of units is not clear unless it hopes thereby to woo farmers gently to decimalization.



How Hoyle found love beyond the Milky Way

IT WILL surprise no one who knows him if this year's top of the pops turns out to have been written by the director of the Institute of Theoretical Astronomy at Cambridge University.

Fred Hoyle's imagination spends most of its time on quasi-stellar objects on the rim of our universe which are burning away at a rate which makes the H-bomb look like a bedroom candle. It's natural territory for a man widely held to be touched with genius.

But now Hoyle is about to show another facet of his diamond-cut talent.

He has written the libretto of a comic opera. Friends who have heard them say the professor's love lyrics are as inspired as most things he turns his hands to.

From an article in the *Daily Mail* (February 2) describing how Professor Hoyle has written the libretto to *The Alchemy of Love*, an opera that will be performed by the Manhattan School of Music in New York next month.

Select Committee gets Under Way

by our Parliamentary Correspondent

THE Select Committee on Science and Technology has begun the first round of this session's main inquiries. Last week, the Registrar General and the Government Chief Actuary were the first to give evidence in the inquiry on population growth, and Sir Stanley Brown and Mr Eric Booth, chairman of the Central Electricity Generating Board and the board's member for engineering, respectively, appeared before the general purposes subcommittee which is investigating the recent failures in electricity generation. This week, representatives from International Computers, Ltd, gave evidence to the subcommittee looking into the UK computer industry.

Sir Stanley Brown said that the failure of the 500 MW generator units, which was responsible for the voltage reductions (or load-shedding) last November, was entirely unexpected, and Mr Booth suggested that the main cause of the failures was lack of attention to design detail. Both agreed, however, that if the generating sets had not been introduced quickly, Britain would have been frozen out of the world market for such equipment.

Responsibility for the failures seems to fall largely on the manufacturers, and Sir Stanley said that the board would not hesitate to order power station plant from abroad if British manufacturers failed to come up to scratch. The CEGB can, of course, impose sanctions on manufacturers in the event of shortfall in performance or lateness, but Sir Stanley denied that the CEGB had not been tough enough with the manufacturers. One turbine company and one boiler company have already been put out of business because the CEGB withheld further orders for plant but, because there are only two suppliers of turbo generators, Sir Stanley agreed that the capacity of both is needed, and that legal sanctions must be made more real.

As far as the corrosion problems of the Magnox reactors are concerned, these seem to be confined to small bolts, clips and straps made from mild steel, and Sir Stanley suggested that they are not a major cause for alarm. The corrosion has, however, reduced the output from the reactors by about 500 MW, because to run them on peak power now would shorten the life of the reactors. The first warnings of the trouble came from research in 1965, but Mr Booth said that the extent of the problem was not realized until 1968, when it was found that the interfaces of bolted joints were becoming corroded.

Commenting on the suggestion from the Select Committee's chairman, Mr Arthur Palmer, that the CEGB seems now to be concentrating more on reducing costs than on striving to maintain voltages, Sir Stanley said that he had hoped that the days of load-shedding were over. Failure of six 500 MW sets cannot pass without notice, however, and Sir Stanley indicated that further voltage reductions may be necessary this winter. That, he said, depends on the weather, and on how much plant is out of action at any given time.

The Select Committee's inquiry into the British computer industry will be undertaken by a subcommittee under the chairmanship of Mr Airey Neave and will concentrate on the possibilities of international collaboration and on the functions of the government, both as policy maker and as a user of computers. It is likely that the Minister of Technology, Mr Wedgwood Benn, will be invited to give evidence personally and, in addition to ICL, IBM and Honeywell will be appearing before the committee. Mr Neave said last week that other interested organizations, including the Atomic Energy Authority, which is a major user of computers, will give evidence later, but that written comments from any source will be welcome.

Professor Douglas, from the School of Computational Method at the London School of Economics, has been appointed special adviser to Mr Neave's subcommittee, and members of the subcommittee all attended a computer appreciation course at Imperial College earlier this month. The subcommittee hopes to complete its investigation by the end of this session.

The other main inquiry, on population growth, is being conducted by a subcommittee under the chairmanship of Mr Arthur Palmer. It kicked off last week with evidence from Sir Herbert Tetley, the government actuary, Mr P. R. Cox, deputy government actuary, Mr M. Reed, registrar general, and Miss J. H. Thompson, chief statistician in the Registrar's Department. In a memorandum to the committee, the witnesses said that the latest estimate for population in the UK in the year 2000 is 68·2 million, and in the next thirty years the average age of the population will decrease. These estimates, are, however, based on many assumptions which, if proved wrong, could significantly affect the figures.

The average number of children per family has remained fairly steady at between 2 and 2·5 between 1931 and 1961, and the estimates for the year 2000 are based on an average family size of 2·5 children. Mr Reed pointed out, however, that a change in family size from 2·5 to 2·25 would reduce the estimate by two or three million. Another factor likely to affect the predictions is a change in the birth rate. This has been far from constant this century. In the 1930s, the birth rate was comparatively low. It rose during the war years and immediately after, but started to fall in the early 1950s. It then rose again in the late fifties and early sixties, but now seems to have levelled off. Miss Thompson suggested that the recovery in the birth rate may be caused by the tendency towards earlier marriage and the increasing percentage of women who get married. Immigration, on the other hand, does not seem to be a significant factor in the projections for the year 2000.

These variations in family size and birth rate are the reason why the estimates of the population in the year 2000 have differed by almost 11 million between 1961 and 1968. In 1961, the Registrar estimated that the population of the UK would reach 63·8 million by the year 2000, but by 1964, this estimate had been revised to 74·7 million, and in 1968 estimates had dropped again to 68·2 million.

NEWS AND VIEWS

150 Years of Astronomy

Astrophilatelists will be delighted that the 150th birthday of the Royal Astronomical Society has not gone unnoticed by the British Post Office. A commemorative stamp is to be issued on April 1, believed to be at a value of 1*s* 9*d*. What the design will be remains, by Post Office tradition, a closely guarded secret until about a month in advance, but those guessing which astronomers or what telescopes are likely to get star billing will remember that the photogenic Mark 1 telescope at Jodrell Bank has already featured on a special issue. At a value of 1*s* 9*d* the stamp will not be publicizing the society on letters within Britain, but it will have a select circulation on first-class parcels weighing 1 lb and air-mailed letters to the United States. Thus the anniversary rates with Sir Francis Chichester's voyage round the world—the society could not have hoped for more.

Astronomers are fond of saying that they are the last gentlemen scientists, and it is true that the monthly meetings of the Royal Astronomical Society provide some of the more delightful moments of the London scientific scene. The gathering of members and fellows for tea in Burlington House beforehand is one of science's social occasions, and often rivals the meeting itself for interest, although this is not likely to be so at the next meeting. This is on February 13 (a Friday, but astronomers are not the type to worry about that) and is to be the official anniversary meeting. As well as a sentimental retrospective of the society's history, there will be the presidential address by Sir Bernard Lovell. The anniversary could hardly have happened at a more exciting time for British astronomy, and no doubt Sir Bernard will have a lot of interesting things to say about the future in his address on the prospects for British astronomy. As well as the upheavals which are going on in our understanding of the universe—the way the theory of supernovae has been stood on its head by the discovery of pulsars, for example—astronomy in Britain is going through an appraisal of priorities which will decide how the subject is to develop for the next few years at least. This is the review of astronomy in the northern hemisphere which the Science Research Council is conducting, and it is pleasing that the Royal Astronomical Society is now taking part. At the pace at which astronomy is going there seems good reason for making the review a frequent event.

Now that the old lecture room with its rogues' gallery of past presidents is being partitioned into smaller rooms, the society meets in the opposite corner of the courtyard of Burlington House in the rooms of the British Academy. There is no denying that this is far from ideal. For one thing, it is now clear that the British Academy room does not make a good lecture theatre. What is more, members are attending meetings without stepping foot inside the society's cramped quarters, and this is a problem which is no doubt exercising the society's council. Unfortunately there is not likely to be a solution until the societies which still inhabit the Burlington House warren are better housed. It is also a shame that although the financial position of the society has been in an encouraging state it is apparently not strong enough to see through the alterations at Burlington House as quickly as might have been hoped. An astronomy society is not the sort of venture which attracts money from industry unfortunately.

With astronomy advancing rapidly on diverse fronts, the Royal Astronomical Society has an important job to do. Astronomy has somehow become fragmented into classifications depending on what techniques are used—there are microwave astronomers, gamma ray astronomers and so on—and the society could be invaluable in bringing them together. The same goes for the new band of lunar scientists, dispersed among departments of physics, chemistry and geology, and waiting for new paths of communication to be established. Clearly there is a lot to be said for more meetings devoted to a particular topic, such as the recent meeting on Mars, where the different disciplines would rub shoulders. Astronomers might well find meetings along these lines more useful than the usual format—generally a hotchpotch of readings from papers accepted for *Monthly Notices*. In any case, with the General Assembly of the International Astronomical Union meeting in Britain this summer for the first time in forty-five years, and with British astronomy booming, the society has a lot to do.

RNA STRUCTURE

Codon and Nodoc

from our Molecular Biology Correspondent

Whereas several spectroscopic methods are available which will give the proportion of paired bases in an RNA chain, and with luck also a good estimate of the relative amounts of A·U and G·C pairs, there has been no dependable way of determining the distribution of paired and unpaired segments along a chain of known sequence. Chemical methods based on the expectation that the paired bases will in general be less reactive than the unpaired have given fragmentary information, but most activity has centred on tortured attempts to deduce unique pairing schemes by earnest contemplation of the sequence, by computer analysis and by some rather desperate model building.

On page 508 of this issue of *Nature* is recorded the birth of a new technique, evolved by Doty and his associates, and based on their studies of base-pair formation between complementary oligonucleotides. The principle is that even complementary sequences of as few as three base pairs will associate to a detectable extent at 0°, so long as at least one pair is G·C. If then tri and tetranucleotides are added to an RNA molecule, they will bind if the chain contains a sequence complementary to the oligomer, and not already involved in intramolecular pairing. The association of each oligomer is measured by equilibrium dialysis, and can be placed into one of three categories, according to its binding propensity—yes, no and perhaps. The last of these one supposes to comprise those oligomers with complementary sequences which, though unpaired, are not sterically favourably placed for the interaction, or are available only in conformational isomers of the native RNA present in low concentration. At all events, the range of binding constants is very large, and at the upper end of the range there is no doubt about the interpretation. To eliminate ambiguities and chart the RNA chain, a range of oligomers with overlapping sequences must be used. The particular beauty of the method lies in the low binding energies that are involved, and make it almost inconceivable that any structures of significant stability in the native RNA could be disturbed by the binding.

The rout of the model builders commences in the first article by Uhlenbeck, Baller and Doty (page 508), which concerns the anticodon loop of formylmethionine tRNA. This has the sequence AAUACUC, with UAC as the anticodon triplet. The latter binds the codon trimer with high efficiency, and the tetramer, AUGA, ten times more strongly yet, showing that the adjoining base on the 5′ side of the anticodon is also available. The tetramer, which overlaps on the 3′ side, UAUG, binds poorly. With a series of trimers and tetramers encompassing the loop sequence and beyond, it is found that only the anticodon triplet and the next two bases on the 5′ side, U and C, are essentially free, the rest not.

Formylmethionine tRNA is known to bind to the ribosome in the presence not only of AUG, but also of GUG, and indeed it turns out that GUG will bind well to the RNA alone. The binding of GUGA, as well as competition between GUG and AUG, shows that the GUG indeed pairs with the anticodon, and this must be seen as the first evidence, beyond the merely circumstantial, that stable G·U pairs really exist. This result also eliminates the notion that GUG binding is a unique aspect of the association of the initiator tRNA with the ribosome. It does, however, point to a special property of the "wobble" position in this sequence, for no other parts of the anticodon loop can be persuaded to participate in G·U pairs.

Lewis and Doty (page 510) have also studied the structure of 5S RNA of *E. coli*, which has a known sequence of 120 nucleotides, by binding experiments with forty-one tri and fifty-seven tetranucleotides. Fifteen of the former and seven of the latter were judged to bind strongly, whereas fourteen and nineteen respectively showed negligible binding, the rest being intermediate. The upshot is that there are four regions, centred around positions 10, 28, 61 and 97, comprising a minimum of twenty-five bases, which are unequivocally unpaired.

The limitations of the method are evident enough: if loops of unpaired bases are constrained by stacking, for example, and packed into a tight tertiary structure, some of the unpaired bases may not be fully available for pairing. On the other hand, there can be no reasonable doubt that the regions at which the oligomers do bind are indeed unpaired in the native structure. This is enough to demolish three different models proposed in the literature for the secondary structure of 5S RNA. Although when the loops have been delineated considerable stretches of complementary sequences can be discerned in the rest of the chain, there is still insufficient information to define the pairing scheme uniquely. Lewis and Doty surmise that it is a complicated affair, which cannot be expressed in two dimensions.

BIOCHEMISTRY

Running into Evolution

from a Correspondent

"You can't work long in biology without running into evolution—it's something that happens to you," said Professor G. Wald (Harvard University) when he gave the opening Feodor Lynen Lecture at the second annual winter symposium of the Department of Biochemistry of the University of Miami and the Papanicolaou Cancer Research Institute in Miami held from January 19 to 23. The title of the first meeting—homologies in enzymes and metabolic pathways—might have promised a hotchpotch of unrelated biochemical observations with a vague evolutionary leaning, but Wald's words provided a theme which was picked up by subsequent speakers. He spoke of classic work ("wrong—but old enough to be forgiven") which identified creatine phosphate or arginine phosphate as a marker differentiating vertebrate from invertebrate metabolism, or of vitamin A_1 or A_2 as distinguishing seawater or freshwater fish. The philosophical arguments between "analogy" and "homology" and the attendant story of "biochemical recapitulation" were themes which every subsequent speaker was obliged to consider.

Sequence differences in species of cytochrome *c*, analysed by Dr E. Margoliash (Abbott Laboratories, Chicago), suggested that although 30 per cent of the residues must always be invariant, any one species can tolerate changes in only 10 per cent of the chain at any one time. One feels that such statistical models of evolution will carry even greater weight when features of the tertiary structures of the proteins can be taken into account.

The selective pressure for sequence changes must lie in the metabolic environment. Phosphoenol pyruvate stands at the gateway of gluconeogenesis, and Professor H. L. Kornberg (University of Leicester) described how bacteria, plants and higher organisms achieve this important metabolic link. Dr W. J. Whelan (University of Miami) showed how animals and plants use different but analogous pathways to break down glycogen or starch, and Dr J. Preiss (University of California, Davis) discussed control of glycogen and starch synthesis. Small variations in mechanisms of fatty acid synthesis were shown by Dr F. Lynen (Munich) to account satisfactorily for the specific fatty acids of various species, and even the bewildering variety of steroid hormones was organized by Dr K. Savard (University of Miami) into a neat set of metabolic compartments. In all these talks it was clear that alternative routes could arise to meet specific metabolic needs of different organisms.

How could such metabolic pathways evolve? Dr E. C. C. Lin (Harvard University) showed how *Aerobacter* "borrowed" a permease from one pathway and a dehydrogenase from another when "learning" to grow on xylitol. Subsequent gene-doubling events would allow selection for greater specificity while preserving the parent pathway. One should expect to find families of enzymes with common mechanisms but different specificities. Dr N. O. Kaplan (University of California, San Diego) gave reason to believe that some dehydrogenases may form such a family, and Dr K. Muench (University of Miami) hinted that amino acyl tRNA synthetases may be another.

Dr B. S. Hartley (University of Cambridge) reminded the participants that the pancreatic serine proteinases are a family with identical conformations of the polypeptide chain, though the surface of these enzymes varies considerably. Yet a single amino-acid change is sufficient to explain the difference in specificity of trypsin and chymotrypsin. Bovine thrombin is similarly homologous with the pancreatic enzymes, but a bacterial proteinase, subtilisin, differs in both primary and tertiary structure. Nevertheless convergent evolution has produced a similar arrangement of catalytic residues in its active site. Dr D. R. Whitaker (University of Ottawa) also told of other serine proteinases from a bacterium and a mould which resemble chymotrypsin rather than subtilisin. Wald's "analogies" and "homologies" appeared as three dimensional molecular models in this symposium.

NUCLEIC ACIDS

Circles not Rolling

from our Cell Biology Correspondent

THE rolling circle model of bacterial and bacteriophage chromosome replication as proposed by Gilbert and Dressler was one of the chief talking points at the 1968 Cold Spring Harbor Symposium on DNA replication (see *Nature*, **219**, 17; 1968). But since then evidence on balance seems to have been running against the rolling circle model as a unitary explanation of the mechanism of chromosome replication in all phages and bacteria.

The model was originally proposed to explain the replication of the single stranded circular chromosome of øX174, and for this phage, and perhaps all phages with similar chromosomes, it still seems valid. Kiger and Sinsheimer (*J. Mol. Biol.*, **40**, 467; 1969) as well as Gilbert and Dressler have detected recently DNA strands longer than complete øX174 chromosomes in infected *E. coli*—the occurrence of such DNA strands is one of the chief predictions of the rolling circle model. On the other hand, attempts to extend the model to the replication of the double stranded circular chromosomes of bacteria, phages and viruses, such as polyoma, have not been convincing. The burden of existing and new experimental evidence, accumulated since 1968, has supported Cairns's model of replication of these chromosomes, which envisages a replicating point moving round a circular DNA unwinding and replicating the complementary strands as it progresses. This model, of course, predicts that the replicating point will be a Y shaped fork and DNA molecules longer than one genome's length should not occur.

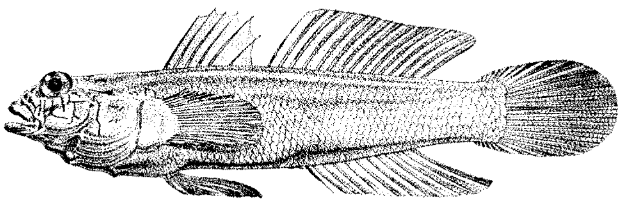
Cairns originally proposed this model to explain his autoradiographs of replicating *E. coli* chromosomes and lately electron micrographs of structures presumed to be replicating λ phage and polyoma chromosomes have been obtained, which are, in essentials, identical to Cairns's autoradiographs. Electron micrographs are, of course, always open to familiar criticisms, but recently Bourgaux, Bourgaux-Ramoisy and Dulbecco (*Proc. US Nat. Acad. Sci.*, **64**, 701; 1969) have reported a centrifugation analysis of replicating polyoma virus chromosomes which is completely consistent with the Cairns model. They have identified a replicative intermediate which is ring shaped, forms a heterogeneous population containing strands of variable length, has nicked DNA, and is larger than the relaxed circular DNA that can be obtained from virions. Moreover, label chases from this intermediate into the superhelical DNA of the virions. All the properties of this replicative intermediate fulfil the requirements of Cairns's model of replication; on the other hand, Bourgaux *et al.* found no evidence of single DNA strands longer than those found in the virus, which should, of course, be present if the polyoma chromosome replicated as a rolling circle.

Some of the conflicting ideas about the replication of λ phage chromosomes have also been resolved recently by Carter, Shaw and Smith (*Biochim. Biophys. Acta*, **195**, 494; 1969). In the past there has been argument as to whether λ DNA replication involves circular molecules or linear concatemers, and the answer seems to be that both forms occur at different stages in the replicative cycle. During the first phase, completed within the first 15 minutes, circular λ chromosomes are replicated, apparently by the Cairns mechanism, to yield covalently closed twisted circular progeny DNA, but these molecules according to Carter *et al.* are never packaged into progeny phage. Indeed, their role is a complete mystery. By 15 minutes after infection linear concatemers up to eight times as long as the λ genome appear and this DNA is fragmented and packaged into progeny phage. Unfortunately the experiments tell nothing about the origin of the concatemers; what data there are are equally consistent with the rolling circle or Cairns model of replication. This means, of course, that the rolling circle model cannot yet be dismissed as irrelevant to replication of λ chromosomes, and the electron micrographs of Cairns type structures isolated from λ infected *E. coli* may be irrelevant to the replication of DNA destined to be packaged into progeny phage. They may simply be pictures of molecules in the first, and apparently abortive, phase of replication.

ICHTHYOLOGY

Another Goby in British Waters

THE discovery that a fish presumed to be absent from British waters has actually been lurking in the shallows of south-west Ireland for at least thirty years is a blow to the complacency of those who like to think that the British fish fauna is thoroughly well known. Gobies are familiar members of the British sea shore fauna and commonly caught by holidaymakers with shrimping nets. But nobody knew that *Gobius cruentatus* came so far north until Dr A. Wheeler of the British Museum (Natural History) found a neglected specimen in the National Museum of Ireland. It had been



Gobius cruentatus from Barlogue Creek, Lough Ine, collected by L. P. W. Renouf in 1930.

there since being found in Lough Ine, County Cork, in 1930 (*J. Fish. Biol.*, **2**, 59; 1970).

Returning to his own museum in London, Wheeler was amazed to find another specimen of *G. cruentatus* hidden away under the name *Gobius niger*. This too dated from 1930, when it was collected in Bantry Bay, County Cork. Wheeler then contacted Professor J. A. Kitching of the University of East Anglia, who had been investigating the ecology of Lough Ine. He produced a collection of gobies, among which Wheeler identified another specimen of *G. cruentatus*.

This species, shown in the illustration, is large, at 166 mm long, compared with most other gobies, and is also distinguished by its large eyes, reddish head and black body. It belongs to the so-called Lusitanian element among fish, being most common in the southern waters around North Africa, Spain and Portugal (which country is roughly equivalent to the ancient Lusitania). The most northerly report of *G. cruentatus* was previously from Arcachon on the French Biscay coast in 1872. It is not altogether surprising that this fish should turn up in Irish waters, where the comparatively warm climate of the southern and western regions provides the northerly limit of distribution of several Lusitanian species.

Three specimens are obviously too few to form the basis of any theory as to how *G. cruentatus* came to Ireland, but the thirty years interval between the capture of Kitching's specimen and the two museum pieces suggests to Wheeler that there is a maintained population in the area. It seems unlikely that specimens could have been carried to the Irish coast by water currents during the planktonic larval stage, for their larval life is rather too short. In any case, currents from the north Spanish coast would not take them to Ireland.

There remains the question of why these gobies have not been found before in the sea around Ireland. The answer seems to lie in their habit of staying concealed just below tide level. Maybe many more are waiting to be found in northerly waters.

ENZYMES

Proline Hydroxylase and Liver

from our Medical Biochemistry Correspondent

The activity of protocollagen proline hydroxylase is increased in healing wounds, fibrotic liver and the skin of growing animals, as a result of the increased rate of synthesis of collagen. The activity of the enzyme might therefore be expected to be intimately connected with the activity of connective tissue. But a recent survey has indicated that it is the liver that is the vital tissue in this respect.

Stein *et al.* (*Lancet*, i, 106; 1970) have developed a technique for assaying proline hydroxylase activity in human serum, and measured the enzyme in twenty healthy volunteers and 124 patients with different conditions. The "normal" range found was from 79–567 d.p.m. per ml. of serum per hour (the amount of tritium released from labelled collagen) and there was no evidence of any increase in activity in patients with diseases of the connective tissues. On the other hand, three patients with hepatomas all had extremely high serum proline hydroxylase activity. Stein *et al.* found that a substantial proportion of patients with hepatitis or cancers with liver metastases had significantly higher than normal serum proline hydroxylase activity. In liver disease there was a good correlation between increased alkaline phosphatase activity and increased proline hydroxylase.

Among patients with cancer, six out of fifteen with lymphoma had increased proline hydroxylase and, of these, four also had increased alkaline phosphatase; eleven out of forty-one patients with other cancers had increased proline hydroxylase, nine of them also having increased alkaline phosphatase.

Elevated serum alkaline phosphatase can also be a symptom of bone disease. It is therefore interesting that in patients with bone metastases, primary bone tumours and Paget's disease, many with great increases in serum alkaline phosphatase, only one patient had slightly more proline hydroxylase than normal.

To investigate whether wound healing would increase proline hydroxylase activity the enzyme was assayed in sixteen patients before and at daily intervals after major surgery. In six patients given nitrous oxide anaesthesia supplemented with muscle relaxants there was no change in proline hydroxylase activity. The other ten patients received either methoxyflurane or halothane as the primary anaesthetic agent, and in all of them concentrations of serum proline hydroxylase increased considerably a few days after the operation. The increase is therefore unlikely to be due to wound healing and may reflect an effect of the anaesthetic on liver metabolism. Both anaesthetics have been suspected of causing liver damage, but these patients showed no evidence of this by any of the conventional tests of liver function.

In view of the finding that serum proline hydroxylase seems to depend on liver activity and not, as might be expected, on the activity of connective tissue, it might prove to be a useful test of liver function; tests used at present are not entirely satisfactory.

STOMATA

Ion Pump at Work

from our Plant Physiology Correspondent

A technique which makes possible direct measurement of the concentration and nature of particular ions in small samples of tissue has provided strong support for the latest theory of stomatal movement. B. L. Sawnhey and I. Zelitch of Connecticut Agricultural Research Station have found that in conditions which favour stomatal opening, potassium ions accumulate in the guard cells. In contrast, an efflux of potassium from the guard cells occurs as the stomata close (*Plant Physiol.*, **44**, 1350; 1969).

Stomata are the minute pores which perforate the epidermal surfaces of leaves and so ventilate the leaf interior. The size of the pore aperture is related to the degree of turgor of the guard cells, two kidney shaped cells which line the mouth of the pore. When the turgor pressure of the guard cells equals that of the surrounding epidermal cells, the guard cells are pressed together, and the pore is closed. In conditions which favour opening, such as light or a decrease in carbon dioxide concentration, the guard cells take up water and become turgid. The peculiar structure of these cells forces them to separate when turgid, and so the pore opens. Stomata are the principal channels for the movement of water and gases between the external atmosphere and the interior of the leaf and, as such, play an important part in regulating the water economy of the whole plant and controlling the rate of photosynthesis.

Economically it would be of great value to be able to regulate either or both of these processes by modifying the stomatal aperture artificially, but more than 100 years of research have not revealed the underlying mechanism. Once it was established that stomatal movement depends on the osmotic movement of water, the problem seemed reduced to a search for a solute which when accumulated in the guard cells could cause an increase in the turgor pressure of these cells, and consequently opening of the pores. It now seems, in the light of recent findings, that the apparently significant presence of chloroplasts in the guard cells has been an appealing but unfortunate red herring. Guard cells are unique among epidermal cells in possessing chloroplasts, the minute green organelles which house the photosynthetic reaction centres. What more likely than that the active solute should be a soluble carbohydrate, produced photosynthetically in the light, but converted into insoluble starch in conditions which favour stomatal closure? Nevertheless, it has proved difficult to find experimental support for this view, and quite recently the work of M. Fujino (*Sci. Bull. Fac. Educ. Nagasaki Univ.*, **18**, 1; 1967), and R. A. Fischer (*Science*, **160**, 784; 1968), has indicated that the movement of potassium ions into and out of the guard cells represents a more likely mechanism.

Sawnhey and Zelitch have used the electron microprobe technique to build up a picture of the accumulation and loss of potassium ions from the guard cells as they open and close in light and darkness. The microprobe focused a stream of electrons onto prepared specimens of plant material causing ions in the material to emit their characteristic X-ray spectra. The spectra were then analysed both qualitatively and quantitatively, and a congruent image of the distribution of particular ions in the samples was obtained. In darkness the pores were closed and no clear pattern in the distribution of potassium in the tissues could be distinguished. After 1·5 hours in the light, however, the concentration of potassium in the guard cells increased from 0·21 M to 0·50 M, and the congruent image shows the open stomata clearly outlined by the accumulation of potassium in the guard cells.

The stomata closed when returned to darkness and the distribution of potassium again became random. The quantitative nature of the electron microprobe technique made it possible to demonstrate a linear relationship between the concentration of potassium ions in the guard cells and the stomatal aperture. Calcium and phosphorus ions were also measured, but these elements showed no regular pattern of movement as the stomata opened and closed.

These results strongly suggest that stomatal movement is controlled by an active transport of potassium ions through the cell membrane of the guard cells. Sawnhey and Zelitch believe that the problem is half solved; the next line of attack must be aimed at elucidating the nature of the ion pump itself.

GEOMAGNETIC FIELD

Spherical Harmonics Superseded?

from our Geomagnetism Correspondent

SPHERICAL harmonic analysis has done sterling service in the cause of geomagnetism during the past hundred years or so. Ever since Gauss carried out the first such analysis in 1839, this has been the standard mathematical technique for representing both the Earth's main field and its secular change. Although a description of the Earth's field in terms of spherical harmonics is a purely mathematical procedure and contains no implication that each term or group of terms corresponds to a different physical effect, other evidence suggests that this is the case. Thus Gauss himself was able to show that although the main field is of internal origin the Earth possesses a very small physically distinct external field. Furthermore, the internal field itself may be divided into dipole and non-dipole components. The different rates of movement of these components with respect to the Earth's surface during the past hundred years suggest that their origins are also different.

In spite of the success of spherical harmonic analysis it remains essentially a mathematical convenience, and so during the past few years attempts have been made to formulate models which are physically more meaningful. As a first step, Alldredge and Hurtwitz (*J. Geophys. Res.*, **69**, 2631; 1964) used a model with a central dipole and eight radial dipoles at a common distance of 0·26 Earth radius from the centre to simulate the field in 1955, and succeeded in reducing the r.m.s. residual of the best fitting field to about 700γ. To reduce this residual field even more, the original model has been extended by Alldredge and Stearns (*J. Geophys. Res.*, **74**, 6583; 1969) to include many more dipole sources. They show that the Finch–Leaton spherical harmonic field for 1955 may be simulated by a central dipole and twenty other dipoles at 0·21 Earth radius from the centre, with an r.m.s. residual of only 28γ. The International Geomagnetic Reference Field (IGRF) for 1965 may similarly be simulated by a central dipole plus thirty-four dipoles at 0·22 Earth radius from the centre, with an r.m.s residual of only 25γ.

Thus in order to represent the Earth's main field, a purely dipole model is as successful as the more familiar dipole–non-dipole spherical harmonic model. But does it describe the secular change field just as well? Apparently it does, for Alldredge and Stearns are able to show that by varying the dipole parameters it is possible to match the Z component of the Finch–Leaton 1955 field with an r.m.s. residual of only $2{\cdot}15\gamma$ per year, and the Z component of the 1965 IGRF with an r.m.s residual of only $1{\cdot}26\gamma$ per year.

So far the new model is as mathematical as spherical harmonic analysis; and there is little evidence that it is physically more realistic. In one sense it clearly is not, for the new models possess dipoles at a distance of about 0·2 Earth radius from the centre, whereas it is widely believed that magnetic changes so deep in the core would not be felt quickly enough at the Earth's surface to account for the observed secular change. Nevertheless, the purely dipole model describes the secular change field remarkably well. For the 1965 IGRF it leads to a westward drift of 0·2 degrees longitude a year, almost identical with the observed westward drift velocity.

The real field sources in the Earth's core are certainly very complex; and a complete understanding awaits a tractable hydrodynamic model. Meanwhile, Alldredge and Stearns hope that their kind of model will lead to a better understanding of the nature of the geomagnetic field and its secular variation without enquiring too deeply into the basic physics of the core motions.

UNUSUAL STARS

Infrared Object which Varies

by our Astronomy Correspondent

There seems to be no easy explanation for the odd behaviour of the infrared object which E. E. Becklin *et al.* of California Institute of Technology have found to be fluctuating in brightness by two magnitudes, equivalent to a factor of more than six (*Astrophys. J. Lett.*, **158**, L133; 1969). The favoured model for several infrared objects in the galaxy—that they are surrounded by a dust cloud which absorbs the energy from the central star and re-radiates it at infrared wavelengths—gives no hint as to why there should be such striking variability. But the magnitude and period of the fluctuation are like that of the Mira variables, and one possibility is that the central star is a Mira variable. The dust cloud would then have to be opaque enough to obscure certain strong absorption bands which are prominent features in the infrared spectra of long period variables but which are absent in the object IRC+10216 under study.

At 5 microns the object is the brightest thing outside the solar system, and clearly it is going to be an embarrassment to infrared astronomy if its nature cannot be cleared up fairly speedily, at least in outline. At visual wavelengths the object is insignificant—fainter than eighteenth magnitude—but on a plate taken by Arp at the 200-inch it has an elliptical non-stellar appearance. It has been observed at 2·2 microns since 1965 using a 62-inch infrared telescope, and these are data reported by Becklin *et al.* The time scale of the brightness variations seems to be 600 days or so.

The location of IRC+10216 is still a mystery. Absence of proper motion and of parallax sets a lower limit on distance of 100 parsec and this is, of course, still within the galaxy. Assuming a distance of 200 parsec—a typical distance for a nearby member of the galaxy—the luminosity comes out to be similar to that of the infrared source in the Orion Nebula and to long-period Mira variables. But Becklin *et al.* cannot rule out that the object is extragalactic, in which case its size as inferred from the 600 day fluctuation places it at 200 kiloparsec with a luminosity comparable with that of the galaxy.

Clearly Becklin *et al.* favour the view that IRC+10216 is in the galaxy, even though it refuses to fit any particular classification. Its similarity to the infrared point source in the Orion Nebula suggests that it may be a protostar, yet it is in an unlikely area where there is no gas or dust and no other young stars, and the brightness variations are awkward. One interesting speculation is that IRC+10216 may be a Mira variable evolving into a planetary nebula, and the clue here is the elliptical nebulosity which surrounds the object.

ELECTRON BEAMS

Electrons for Carrying Light

Two members of the Signals Research and Development Establishment at Christchurch have suggested an explanation for an apparently mystifying effect discovered in an electron diffraction experiment (Schwarz and Hora, *Appl. Phys. Lett.*, **15**, 11; 1969, reported in *Nature*, **225**, 15; 1970). The effect is that if a beam of electrons is diffracted by a thin crystal film of silicon or aluminium oxide through which a laser beam is shone at right angles to the electron beam, the diffraction pattern seen on a non-fluorescent screen of alumina contains spots of the same colour as the light in the laser beam. Drs R. L. Harris and R. F. Smith write:

It appeared to us, at first sight, not particularly surprising that the effect should have been observed. Indeed, analogous interactions between electromagnetic waves and electron beams have been used for some time in devices such as klystrons. Energy at the electromagnetic wave frequency is carried by the electron beam as velocity modulation, resulting in bunching which varies in intensity with distance along the beam.

But, on closer inspection, bunching as it is normally understood cannot directly cause the observed effect. This conclusion was reached by consideration of the electron density in the beam. Using the figures given by Hora and Schwarz, we calculated a value of 500 electrons per centimetre of the beam. A typical figure for the klystron would be between 10^4 and 10^6 times this value, and the modulating wavelength would be, say, 1 cm. In the case of light, the wavelength is only about 4×10^{-5} cm, and so the electrons are, on average, separated by many wavelengths. In spite of this, the effect may still be explained by velocity modulation if bunches of electrons occur separated in time by integral numbers of periods of the original optical wave. This requires the recovery process in the screen to be non-linear, thus producing harmonics of the electron bunching frequency.

If the effect is due to velocity modulation, then movement of the screen along the axis of the electron should result in a periodic variation in intensity of the optical emission from the screen. Because the distances between these peaks of intensity are dependent on the velocity of the electron beam, the reported reduction in intensity of the optical images with a decrease in electron velocity is possible for a particular position of the screen.

The reported disappearance of the effect on rotation of the plane of polarization of the incident light is to be expected if the velocity modulation explanation is true.

Fairly simple experiments can be devised to disprove the velocity modulation explanation, and this should be done before more erudite explanations involving "modulation" of individual electrons are proposed.

Extra-galactic Distance Scale

by

SIDNEY VAN DEN BERGH

David Dunlap Observatory,
University of Toronto,
Richmond Hill, Ontario, Canada

Nine different methods are used to determine the value of the Hubble constant. A mean value $H = 95^{+15}_{-12}$ km s^{-1} Mpc^{-1} is obtained from all data that are now available.

THE determination of the extra-galactic distance scale is essentially a two step process. First the distances to nearby galaxies which are members of the Local Group have to be determined. Next these nearby galaxies are compared with galaxies which are at such large distances that their systematic velocities of recession are large compared with their random motions.

Data on the distances to galaxies of the Local Group[1] are summarized in Table 1. The final distance moduli which are adopted for M 31 and the Magellanic Clouds depend rather critically on the relative weights that are given to different methods of distance determination. A weight of three has been assigned more or less arbitrarily to moduli derived from Cepheids, a weight of two has been given to moduli obtained from novae and RR Lyrae stars, and unit weight has been assigned to distance moduli determined from W Virginis stars, Population II giants, globular clusters, MK classifications and Hβ and Hγ photometry. It should perhaps be emphasized that the resulting distance moduli of the Local Group members depend rather critically on the assumption that the Cepheids in all galaxies obey a universal period-luminosity relation.

All determinations of distances beyond the Local Group are ultimately based on the assumption that recognizable types of distant objects are similar in nearby and in distant galaxies of the same type. This assumption may not be correct for any particular type of distance indicator because of possible differences in age, evolutionary history and abundance of the elements. Systematic errors due to such differences will be minimized if the largest possible number of methods of distance determination is used.

Nine distinct methods of distance determination beyond the Local Group are now available. The internal agreement between the distances obtained by these different methods provides some indication of the degree of confidence which may be placed in the resulting distance scale.

Diameters of HII Regions

Measurements of the diameters of HII regions on plates obtained with the 100 inch and 200 inch telescopes have been reported by Sérsic[2]. Unfortunately only blue plates, on which the contrast between nebulae and background is often quite small, were available in this study. A comparison of the mean diameters of the three largest HII regions in Local Group galaxies with the mean diameters of the three largest HII regions in thirteen distant galaxies of types Sc$^+$, dSc and Ir yields a value of $5 \log (H/100) = -0{\cdot}2 \pm 0{\cdot}4$, which corresponds to $H = 91^{+19}_{-15}$ km s^{-1} Mpc^{-1}. A more detailed study of giant emission regions in extra-galactic nebulae is currently in progress at the Mt Wilson and Palomar Observatories.

Luminosity Classification of Galaxies

Observation shows that the degree to which spiral structure is developed in galaxies correlates strongly with absolute luminosity. Intrinsically bright spirals are found to have long and well developed spiral arms whereas intrinsically faint spirals show only a rudimentary and ill defined spiral pattern. From a comparison of the luminosity classifications[3-5] of distant spiral nebulae with the luminosity classifications of the Local Group members M 31 and M 33, a value of $5 \log (H/100) = -0{\cdot}05 \pm 0{\cdot}4$, which corresponds to $H = 98^{+19}_{-17}$ km s^{-1} Mpc^{-1}, is obtained. The chief uncertainty of this result is due to the fact that only two Local Group galaxies are available for calibration.

Brightest Globular Clusters in Galaxies

Because of their high luminosities, globular clusters can be seen out to very large distances. This makes globulars potentially valuable as calibrators of the extra-galactic distance scale[6]. It should, however, be emphasized that the assumption that the brightest globular clusters in different galaxies have exactly the same luminosity is as yet unproven. The brightest galactic globular cluster is ω Centauri[7] for which $M_B = -9{\cdot}7$ if $\langle M_B \rangle = +0{\cdot}8$ is adopted for the RR Lyrae stars in this cluster. This is significantly fainter than the value $M_B = -10{\cdot}05$ obtained from recent 200-inch observations of the cluster Mayall II in M 31. (The clusters Nos. 39, 42, 93 and 327 in M 31 have luminosities which are comparable with that of MII. The data for M 31 and the galaxy yield a mean absolute magnitude $\langle M_B \rangle = -9{\cdot}88$, with an uncertainty of, say, 0·3 magnitudes, for the brightest globular clusters in supergiant spirals. This value may be compared to $B = 21{\cdot}2 \pm 0{\cdot}2$ which Racine[8] obtains for the brightest globular clusters in the supergiant elliptical galaxy M 87 in the Virgo cluster. If it is assumed that the brightest globulars in M 87, M 31 and the galaxy have the same absolute luminosity, then $(m-M)_{\text{pg}} \simeq (m-M)_0 = 31{\cdot}08 \pm 0{\cdot}36$ for the Virgo cluster. Combining this value with the mean observed[9]

Table 1. APPARENT VISUAL DISTANCE MODULI OF LOCAL GROUP GALAXIES*

Method	LMC	SMC	M 31	M 33	NGC 6822	IC 1613
Cepheids	19·0 ± 0·10	19·52 ± 0·10	24·66 ± 0·13	24·64 ± 0·14	24·78 ± 0·2	24·82
Novae	19·39 ± 0·4	19·42 ± 0·15	24·49 ± 0·12	—	—	—
RR Lyrae stars	18·65 ± 0·2	19·10 ± 0·2	—	—	—	—
W Virginis stars	—	19·31 ± 0·15	24·74 ± 0·10	—	—	—
Pop. II giants	18·37 ± 0·5	19·05 ± 0·5	24·40 ± 0·3	—	—	—
Globular clusters	—	—	23·9 ± 0·1	—	—	—
MK classification	18·70 ± 0·3	—	—	—	—	—
Hβ + Hγ	18·20 ± 0·4	18·49 ± 0·3	—	—	—	—
$\langle m-M \rangle_v$	18·84 ± 0·17	19·24 ± 0·14	24·50 ± 0·13	24·64	24·78	24·82
V	0·1	2·3	3·5	5·7	8·5	9·6
M_v	−18·7	−16·9	−21·0	−18·9	−16·3	−15·2
A_v (foreground)	0·18	0·06	0·33	0·09	0·57	0·09

* Errors quoted for each method are internal mean errors.

radial velocity of the Virgo cluster, $< V > = 1{,}175 \pm 64$ km s^{-1}, yields a value of 5 log $(H/100) = -0{\cdot}7 \pm 0{\cdot}4$. This corresponds to $H = 72^{+15}_{-12}$ km s^{-1} Mpc^{-1}. This value depends critically on the assumption that the brightest globular clusters in giant spiral and giant elliptical galaxies have exactly the same absolute luminosity.

Mass-to-light Ratios

Recently, Roberts[10] and Vorontsov-Velyaminov[11] have discovered that the mass-to-light ratios of spiral and irregular galaxies do not depend on their Hubble type. Furthermore, Roberts's data show no clear-cut correlation between the luminosity and the mass-to-light ratio of galaxies. This result implies that the extra-galactic distance scale may be obtained by comparing the mass-to-light ratios of distant galaxies with the presumably rather well known mass-to-light ratios of Local Group members. The mass of a galaxy, as determined from its rotation curve, is proportional to the assumed distance D whereas the absolute luminosity of a galaxy is proportional to D^2 so that $\mathcal{M}/L \sim D^{-1} \sim H$. Reducing Roberts's data to the distance scale in Table 1 yields $< \log(\mathcal{M}/L) > = 0{\cdot}63 \pm 0{\cdot}11$ for the spiral and irregular galaxies in the Local Group. Substitution of this value into $< \log(\mathcal{M}/L) > - \log(H/100) = 0{\cdot}61 \pm 0{\cdot}05$, which is obtained from Roberts's data for sixty galaxies with distances smaller than four Mpc, yields 5 log $(H/100) = +0{\cdot}1 \pm 0{\cdot}6$. This value corresponds to $H = 105^{+33}_{-26}$ km s^{-1} Mpc^{-1}.

Third Brightest Cluster Galaxy

A very rough estimate of the value of the Hubble constant can be obtained by comparing M 33, which is the third brightest member of the Local Group, with the third brightest galaxies in other small clusters of galaxies. From inspection of the Palomar Sky Survey it is found that the small clusters associated with NGC 3227, NGC 3368 NGC 3627 and NGC 4274 probably resemble the Local Group rather closely. Comparison of the third brightest members of these small clusters with M 33, for which $M_B = -18{\cdot}2 \pm 0{\cdot}5$, yields 5 log $(H/100) = +0{\cdot}5 \pm 0{\cdot}7$ which corresponds to $H = 126^{+48}_{-35}$ km s^{-1} Mpc^{-1}. It should be emphasized that this value is based on the unproven assumption that all small clusters of galaxies have similar luminosity functions. Furthermore, this determination of H involves a subjective choice of clusters which are believed to be similar to the Local Group.

Supernovae and the Extra-galactic Distance Scale

Distant supernovae can be compared directly with the supernovae in our own galaxy without using the members of the Local Group as intermediate stepping stones. Unfortunately, little is known about the intrinsic dispersion in the absolute magnitudes of different types of supernovae at maximum light. Furthermore, only fragmentary information is available on most of the supernovae that are known to have occurred in the galaxy during the last 1,000 years.

Table 2. COLOUR OBSERVATIONS OF TYCHO'S SUPERNOVA

Date	Colour	Adopted $B-V$	$(B-V)_0$	A_V
Nov. 1572	Like Venus ($B-V = 0{\cdot}83$) and Jupiter ($B-V = 0{\cdot}82$)	0·82	$0{\cdot}3 \pm 0{\cdot}1$	1·64
Jan. 1573	Similar to Mars ($B-V = 1{\cdot}36$) and Aldebaran ($B-V = 1{\cdot}52$)	1·44	$1{\cdot}0 \pm 0{\cdot}1$	1·48
Apr. 1573	Similar to Saturn ($B-V = 1{\cdot}04$)	1·04	$0{\cdot}5 \pm 0{\cdot}1$	1·75

Neither the maximum apparent magnitude nor the distance to the supernova of AD 1006 in Lupus is accurately known. According to Minkowski[12] the Crab supernova of 1054, for which both the distance and the apparent magnitude at maximum light are reasonably well known, seems to have been an unusual object for which no extra-galactic counterpart is known with certainty. In the case of Kepler's supernova of 1604, both the apparent magnitude at maximum light and the reddening are known but the distance is not. Finally, the supernova[13] of 1667, which produced the radiosource Cassiopeia A, was not seen by seventeenth century observers because of excessive interstellar absorption. Only Tycho's supernova of 1572 was sufficiently well observed to permit a rough estimate of the extra-galactic distance scale. From a definitive study Baade[14] obtained $V = -4{\cdot}0 \pm 0{\cdot}3$ for the maximum apparent magnitude of a Tycho's supernova. The reddening suffered by this supernova is surprisingly well determined from the colour estimates given by sixteenth century observers. A comparison of the observed colours with Mihalas's[15] intrinsic colours of type I supernovae is given in Table 2. The data in the table give $A_V = 1{\cdot}62$ with a formal mean error of about 0·1 magnitudes. Adopting this value for the absorption yields V_0 (max) $= -5{\cdot}62 \pm 0{\cdot}32$. From a comparison of observations of 21 cm absorption lines with rotation models of the galaxy (ref. 16 and unpublished work of Minkowski) the distance of the supernova is found to be greater than 3·0 kpc but probably less than 3·5 kpc, that is $(m-M)_0 = 12{\cdot}56 \pm 0{\cdot}16$. Combining this with the value with V_0 (max) $= -5{\cdot}62 \pm 0{\cdot}32$ yields M_V(max) $= -18{\cdot}18 \pm 0{\cdot}36$. Comparison of this value with the mean absolute magnitude of type I supernovae given by Kowal[17,28] yields 5 log $(H/100) = +0{\cdot}45 \pm 0{\cdot}7$, which corresponds to $H = 123^{+47}_{-34}$ km s^{-1} Mpc^{-1}. This estimate, which is based on ancient observations of a single supernova, is of course highly uncertain.

Surface Brightness and Diameter of Galaxies

Holmberg[18] has shown that the surface brightness of spiral galaxies correlates with their intrinsic luminosity. In the mean, bright galaxies have a higher surface brightness than do faint galaxies. Intercomparison of the surface brightnesses of M 31 and M 33 (both corrected for galactic intersteller reddening) and the surface brightnesses of galaxies in the Virgo cluster (for which $< V > = 1{,}175 \pm 64$ is assumed) yields 5 log $(H/100) = -0{\cdot}15 \pm 0{\cdot}9$. This corresponds to $H = 93^{+48}_{-31}$ km s^{-1} Mpc^{-1}. The rather large mean error of this result is due to the large cosmic dispersion in the relation between the surface brightness and absolute magnitude of galaxies.

It is well known that intrinsically bright galaxies have larger diameters than do faint galaxies. Heidmann[19] has shown that the relation between the luminosity and diameter of galaxies may be used to estimate the Hubble constant. Comparison of Holmberg's[18] observations of galaxies in the Virgo cluster with the known absolute magnitudes and linear diameters of M 31, M 33, the Large Magellanic Cloud and Small Magellanic Cloud yields 5 log $(H/100) = -0{\cdot}25 \pm 0{\cdot}9$, which corresponds to $H = 89^{+46}_{-30}$ km s^{-1} Mpc^{-1}. The Local Group dwarf NGC 6822 has not been included in this comparison because extrapolation of its diameter to zero reddening is both large and uncertain. The dwarf galaxy IC 1613 was excluded because the validity of the relation between log diameter and m_{pv} in the Virgo cluster has not been established for such intrinsically faint galaxies.

Elliott's GX3 rotating anode X-ray diffraction equipment includes an exclusive fine focus cathode system with a rotating anode of high power loading capability. 7 kW/mm^2 (actual area) is available with one thousand hours filament life. The plant includes the rotating anode tube mounted on a robust console which houses the vacuum system, cooling system and all controls. Tube current and voltage are stabilised within ±0·1%. Focal spot sizes are easily interchanged without disturbing the filament and advanced long-life seal design ensures trouble-free operation from the dynamically balanced anode.

ACRYLIC chromatography columns

versatile inexpensive laboratory columns for chromatographic and gel filtration procedures employing aqueous solvents

Simple to use—unique patented design in acrylic and nylon with sintered plastics bed support.
Minimal dead space with low-volume connections. Diameters selected to produce cross-sectional area of 2, 4, 8, & 16 sq. cms.
Fixed or adjustable columns with or without jackets.
Standard lengths of 30, 60 and 90 cms.
Columns easily lengthened by joining.
Prompt delivery of standard columns from stock.
Preparative columns with bed volumes up to 50 litres are available to special order

Prices from **£5**

Cambridge Journals

Experimental Agriculture

Edited by Professor
J. P. HUDSON, *Wrington, Bristol*

This journal publishes the results of experimental work in animal and crop husbandry, with particular emphasis on problems in tropical countries. It includes accounts of new experimental techniques, and review articles on new developments in scientific agriculture.
Annual subscription (four issues) £5 ($16.50 in the USA). Single parts 35s ($5.00 in the USA).

Archaeometry

Edited by Mrs J. REID,
Richmond
Managing Editors:
Dr M. J. AITKEN and
Dr E. T. HALL, *Oxford*

Archaeometry is the only research journal devoted to applications of the natural sciences in archaeology. It includes work on dating methods, locating devices, archaeo-magnetic measurements, and analyses of coins and other artefacts.
Annual subscription (two issues) £3 ($9.50 in the USA). Single parts 40s ($6.00 in the USA).

The Journal of Hygiene

Edited by Dr R. M. FRY,
Department of Pathology, Cambridge

The Journal of Hygiene is concerned with bacterial and virus diseases of man and animals, and particularly with the identification of pathogens, epidemiology, and immunology.
Annual subscription (four issues) £7 ($23.00 in the USA). Single parts 40s ($6.50 in the USA).

The British Journal of Social and Clinical Psychology

Edited by Professor
THELMA VENESS
University of London Institute
and Dr J. G. INGHAM
Llandough Hospital, Penarth

Published for the British Psychological Society, the journal contains articles and book reviews on social psychology, criminology, psychotherapy, personality measurement and related topics.
Annual subscription (four issues) £6.10.0 ($22.00 in the USA). Single parts 45s ($7.50 in the USA).

Please write for further information and specimen copies of these, or any other journals published by the Press. Details of available back issues will also be sent on request.

Brightest Stars in Galaxies

For galaxies with redshifts smaller than about 1,500 km s^{-1} the brightest individual stars may be used as distance indicators. In 1953 Hubble and Sandage[20] suggested that the brightest blue variables in galaxies might prove to be useful in this way. Recent observations by Tammann and Sandage[21], however, indicate that these blue variables may have a considerable range in luminosity at maximum light. In fact it seems quite probable that the brightest blue irregular variables form a continuum which bridges the gap between the brightest stable main sequence stars and supernovae of type II.

Table 3. SUMMARY OF DATA ON THE HUBBLE CONSTANT

Method	5 log (H/100)
Diameters of HII regions	-0.2 ± 0.4
Luminosity classifications of galaxies	-0.05 ± 0.4
Brightest globular clusters in galaxies	-0.7 ± 0.4
Mass-to-light ratios of galaxies	$+0.1 \pm 0.6$
Third brightest member of small clusters	$+0.5 \pm 0.7$
Tycho's supernova	$+0.45 \pm 0.7$
Surface brightness of galaxies	-0.15 ± 0.9
Diameters of galaxies	-0.25 ± 0.9
Brightest stars in galaxies	$+0.1 \pm 1.0$
Adopted mean*	-0.1 ± 0.3

* Corresponds to $H = 95^{+15}_{-12}$ km s^{-1} Mpc^{-1}.

The brightest non-variable stars of Population I may be used as distance indicators after allowance has been made for the fact that the absolute magnitudes of these stars depend on both nebular type and on total Population I content. In practice additional difficulties arise because bright star clusters cannot be distinguished from individual stars of high luminosity. Furthermore, the bright end of the steller luminosity function is thinly populated with stars so that the statistical separation of truly extragalactic stars of high luminosity from foreground field stars is uncertain. Determinations of the absolute magnitudes of the brightest stars in the members of the Virgo cluster are at present in a thoroughly unsatisfactory state. Perhaps the best guess that can be made from a comparison of the brightest stars in the Virgo cluster with the brightest stars in M 31 and M 33 is that $(m-M)_{pg} = 30.25 \pm 1.0$ for the Virgo cluster. The assumption of zero reddening and a mean cluster velocity $<V> = 1,175 \pm 64$ km s^{-1} Mpc^{-1} yields $5 \log (H/100) = +0.1 \pm 1.0$. The corresponding value of the Hubble constant is $H = 105_{+51}$ km s^{-1} Mpc^{-1}. The uncertainty of this value could be significantly reduced by new photoelectrically calibrated measurements of the brightest stars in Virgo cluster galaxies.

Tammann and Sandage[21] have recently suggested that the brightest red stars of Population I might be useful distance indicators. The possibility that the absolute luminosity of such highly evolved stars might be very sensitive to the effects of chemical composition[22,23] should, however, be kept in mind.

The results of all nine methods of distance determination which are currently available have been summarized in Table 3. Assigning weights that are inversely proportional to the squares of the mean errors quoted for each method yields $5 \log (H/100) = -0.14 \pm 0.19$.

The nine methods of distance determination listed in Table 3 are not entirely independent. This is so because all methods, except that based on supernovae, depend on the distance scale within the Local Group. This distance scale is particularly sensitive to the zero point that is adopted for the Cepheid period-luminosity relation. For example, making all Cepheids brighter by 0·2 magnitudes would change H from 95 to 100 km s^{-1} Mpc^{-1}. A change of 10 per cent in the adopted distance to the Virgo cluster would change the Hubble constant by approximately 5 per cent. A final value of $5 \log (H/100) = -0.1 \pm 0.3$, which corresponds to $H = 95^{+15}_{-12}$, will be adopted. The quoted mean error makes allowance for the interdependence of the nine methods of distance determination listed in Table 3.

Regional Variations of the Hubble Constant

Available data on the distances and velocities of galaxies[24] suggest that individual galaxies have random velocities of the order of 200–300 km s^{-1}. The velocity of the galaxy relative to the absolute reference frame provided by the 3° K microwave radiation[25] is also of this order. The value of the Hubble constant determined here is particularly sensitive to possible random motions of clusters of galaxies in the vicinity of the Local Group, that is the locally determined value of H may not be representative of the universe as a whole.

Recently, Sandage[26] has shown that the absolute magnitude of the brightest member of rich clusters of galaxies exhibits a dispersion of only 0·3 magnitudes. A comparison of NGC 4472, which is the brightest galaxy in the Virgo cluster, with Sandage's data on the brightest galaxies in distant clusters yields $H(0)/H(\infty) = 1.04 \pm 0.15$ in which $H(0)$ is the local value of the Hubble constant and $H(\infty)$ is the Hubble constant beyond the Local Supercluster. Taken at face value this result indicates that there is no systematic difference between the Hubble flow inside and outside the Local Supercluster. Similar results, of rather lower accuracy, are obtained by Kowal[17,28] from a comparison of supernovae in the Virgo cluster with more distant supernovae. A rather different conclusion, however, is obtained by Abell and Eastmond[27], who compared the galaxian luminosity function of the Virgo cluster with the luminosity functions of the Coma and Corona Borealis clusters. Additional observations comparing the expansion of nearby space with the Hubble flow in more distant regions of the universe are clearly available.

I thank Dr Allan Sandage for several stimulating discussions on the time scale of creation.

Career Choices by Science Studies Students

by
D. O. EDGE
Science Studies Unit,
University of Edinburgh,
34 Buccleuch Place,
Edinburgh EH8 9JT

Graduates who took science studies at Edinburgh are more likely to choose careers in industry and commerce than specialist science students. The decision to take a course of this type may reflect a prior career decision.

THE Faculty of Science in the University of Edinburgh initiated in October 1967 a one-year course in science studies as an option in the curriculum of science students. It is an introduction to some of the social and intellectual implications of the rise of modern science and technology; the material is selected from studies in history, philosophy, sociology and political science, and the topics are related so as to explore the social nature of science (the course is described in the Science Studies Unit's First Report, 1966–69). The course is usually taken in the student's second or third year (the honours year in Scotland is the fourth), and occupies half the time for that year. It is a "generalist" course, in the sense of the Swann Report when it mentions "interweaving several diverse disciplines to show their inter-relationships and relevance . . ."[1]. Some information about the career choices of those who take this course is now available.

Table 1. CAREER CHOICES OF GRADUATES

Group	Category *a*	 *b*	 *c*	 *d*
Science studies group	12	4*	4	4
Reference group	5	12	1	6†

* If PhD in clinical psychology included, add 1.

† Includes one graduate doing teaching temporarily, while trying to make a career in journalism.

Of the fifty-five students who registered for the initial course in 1967/68, twenty-three were in their third year at university and were intending to go on to honours in science (the honours schools involved were botany, chemistry, geography, geology, physics and psychology); a further two students were in the second year of an ordinary (3 year) degree course. Twenty-five students were therefore due to graduate in the summer of 1969. We have attempted to compare the career choices of these students with a reference group of science students who, in October 1967, had similar degree intentions but did not choose to take the science studies course nor any of the other "complementary" courses then available (history of science or economics). The reference group was matched to the science studies group within each honours school by number and sex, individuals being selected at random from the relevant pools of students not taking science studies.

Students in both groups were asked to state their plans for 1969/70 as soon as these were known. They were also asked about their long term career plans (if any), to find out what careers they had in mind, and how firmly they were committed to these plans. Members of the science studies group were also asked whether the science studies course had any influence on their career decisions; responses to this question were coded from *A* (crucially) to *E* (not at all).

From the results of the questionnaire, the "immediate destinations" of the graduates can be grouped into the following broad categories. (*a*) Those going directly into industrial or commercial employment, or undergoing short term training explicitly designed for such employment. Because the numbers involved are small, this includes those going into government employment (an administrative post with the Science Research Council, a scientific officer at the Ministry of Defence, an experimental officer with the Ministry of Overseas Development in Malawi, and a physicist in the British Antarctic Survey—two of these were from the science studies group, and two from the reference group). It also includes two graduates emigrating to Australia in search of professional scientific jobs: one a geologist (science studies), and one a chemist (reference); and a chemist (reference) who is abandoning chemistry to study accountancy and computer techniques for an industrial career. (*b*) Those going into postgraduate training which could lead to an academic career, whether or not that is their expressed long term preference. (*c*) Those preparing for clinical or social work. This category includes one graduate (science studies) who is studying for a PhD in clinical psychology and could be classified under (*b*) although his long term career preference is not academic. (*d*) Those going into school-teaching, or teacher training.

The destination of one science studies student is unknown. The matched figures are shown in Table 1.

Twenty-four students in the science studies group ventured subjective estimates of the influence of the course on their career choices. The distribution of these estimates is given in Table 2.

Table 1 shows that science students who choose to take, and who successfully complete, the science studies course are more likely to proceed directly into industrial and commercial employment and less likely to pursue an academic career than their strictly specialist counterparts. Table 2 suggests that this tendency might be, at least in part, a result of the course itself. These subjective estimates are, however, likely to over-stress the effect of the course: there is evidence that many respondents were "eager to please". Moreover, further elaboration of these figures exposes a more complex situation.

Graduates in category (*a*) can be subdivided into (i) those going to practise as scientists in manufacturing industry (including oil and chemical industries), (ii) those going to practise as scientists elsewhere (for example, in government service), (iii) those going into technical and production management, and (iv) those going into general administration, personnel management, marketing, cost accountancy and so on.

Table 2. SUBJECTIVE ESTIMATE OF INFLUENCE OF COURSE ON CAREER DECISION

	Class				
	A	*B*	*C*	*D*	*E*
No. of responses	4	4	4	6	6

Table 3 shows the results of this subdivision, together with the subjective estimates of course influence. It seems that, if the science studies course has any influence on career choice, it serves chiefly to deflect scientists, not into the practice of science elsewhere, but into the general field of management. Those embarking on a career as "applied scientists" tend to give low estimates of the course's influence. Their replies indicate that many of them had made their career decision before starting the course, and that they chose to take the course because of its likely relevance to that career.

Table 3. DESTINATION OF GRADUATES IN CATEGORY (*a*)

Destination subdivision	Reference group	Science studies group
(i)	1	4 (1*A* †, 2*D*, 1*E*)
(ii)	3*	3* (1*C*, 2*E*)
(iii)	0	1 (1*E*)
(iv)	1	4 (1*A*, 3*B*)

* Includes one emigrant to Australia.

† This graduate expressed a long term commitment to abandon science for personnel management.

Of the twelve graduates in the reference group in category (*b*), seven expressed a long term preference for an academic career, two for a non-academic career and three were undecided. Of the five science studies graduates who could be included in this category, two (one *D*, one *E*) had non-academic aims. Only one had chosen an academic career; he assessed himself to have been "considerably" influenced by the course, and it is known that he gave very long and careful thought to his decision.

The distribution of estimates of influence by the science studies students in the other two categories is given in Table 4.

Table 4. ESTIMATES OF GRADUATES IN CATEGORIES (*c*) AND (*d*)

	Estimate				
Category	*A*	*B*	*C*	*D*	*E*
Social and clinical	1	0	1	1	1
Teaching	0	0	2	1	1

Returning to a consideration of the whole sample, one important difference between the two groups might be found in their eventual academic attainments, as measured by their degrees and final honours classes. This may partly account for the differences expressed in Table 1: those who do not obtain good second class degrees are not offered the chance of postgraduate work, eventually leading to an academic career, and they must decide otherwise.

Of the twenty-three students in the science studies sample who originally intended to take honours degrees, eleven did not proceed to honours and graduated with an ordinary degree in the summer of 1968; the corresponding figure in the reference group is five. Failure to proceed to honours can result from academic failure, but it can also be a deliberate choice by the student. Of the eleven science studies ordinary graduates, it would seem that at least four (one *D*, three *E*) were taking a "short cut" to a career already decided on; one (*E*) was the result of serious illness; and not more than three (one *A*, two *B*) were deliberate choices to switch from honours science (to management, in all three cases).

(The notion of "deliberate choice" is, of course, problematical. It may arise from the genuine perception of a more desirable career; or it may be merely an honest, if perhaps unconscious, estimate of the likely honours class. The two are not unrelated. An able student may be influenced by devoting less time to his principal science subject; this will be reflected in his ongoing performance and so will alter his assessment of his likely degree class. This may lead to a decreasing interest in honours science, a resulting increasing interest in something else, and, finally, a "deliberate choice". Neither level of interest, nor expectation of degree class, is necessarily a measure of intrinsic ability.)

Twelve science studies students and eighteen students in the reference group proceeded to honours. Any significant difference between these groups could be detected only by dividing the second class honours degree, but this is not the practice at Edinburgh. Some information made available to the author suggests, however, that the science studies group may have contained a relatively smaller percentage of good second class degrees. The difference is not significant, but it is not inconsistent with the suggestion that career decisions and the related decision to take the science studies course may reflect the student's assessment of his likely degree class.

This small sample and informal survey therefore seems to provide some evidence both for the suggestion that the decision to take a generalist course of this type reflects a prior career decision, and that such a course helps to influence (perhaps to "crystallize") career decisions. More detailed research into career choice by science students is being conducted by Mr S. B. Barnes in the Science Studies Unit.

I thank Mr D. C. Bloor, Mr S. B. Barnes and Mr L. E. Schwartz for helping to create the science studies course, and the Wolfson Foundation, whose grant led to the foundation of the Science Studies Unit.

Complementary Oligonucleotide Binding to the Anticodon Loop of fMet-transfer RNA

by

OLKE C. UHLENBECK*
JULIE BALLER†
PAUL DOTY

Department of Biochemistry and
Molecular Biology,
Harvard University, Cambridge, Massachusetts

Exposed, unpaired areas of an RNA molecule will bind complementary tri and tetranucleotides. The binding can be measured by dialysis equilibrium methods and if the RNA sequence is known the conformation of the molecule can be mapped. The method is here applied to the anticodon loop of formylmethionine tRNA.

STUDIES of the stability of helical complexes formed from short self-complementary oligonucleotides (O. C. U., F. H. Martin and P. D., manuscript in preparation) suggest that oligonucleotides of only three or four units should interact with available complementary regions of an RNA molecule to such a degree that the association constant could be readily measured by conventional dialysis equilibrium. With the use of suitable controls and a variety of oligonucleotides it should therefore be possible to identify the open, unshielded and unpaired regions of an RNA molecule of known sequence. We report here the development of the methodology and its use in defining which bases are available in the anticodon loop of $\mathrm{tRNA}^{\mathrm{Met}}_{\mathrm{f}}$. The article which follows this demonstrates the extension of the method to the mapping of the whole length of 5S RNA[1]. It is apparent that this method cannot be used to detect available sequences shorter than its shortest probe, three nucleotides. In this way it complements chemical methods which generally recognize single unshielded bases. It must also be expected that sequences held in a rigid single-stranded conformation incompatible with bihelical conformations will not be identified. Thus the available sequences identified may be somewhat less than the total not in bihelical regions.

The anticodon loop of transfer RNAs of known sequence provides a useful prototype for evaluating the techniques of oligomer binding. The reactivity of this loop to reagents specific for single stranded residues[2,3] and ribonucleases[4] and the absence of complementary sequences prove that this loop is not involved in secondary or tertiary structure. Our concern is to explore the availability of the bases within the loop, and adjacent to it, for helix formation.

A study of the interaction of oligomers with tRNA can also be useful in determining whether the properties of the codon–anticodon interaction are the same as those observed for tRNAs and oligomers interacting in the presence of ribosomes. In particular, $\mathrm{tRNA}^{\mathrm{Met}}_{\mathrm{f}}$ has been found to bind to ribosomes in the presence of either AUG or GUG[5]. This ambiguity could be explained by hypothesizing a G·U base pair at the 5′ position of the codon rather than at the 3′ position[6]. Experiments in the absence of ribosomes would thus determine whether the observed relaxation of the specificity of base pairing is the result of the particular environment supplied by the ribosome or is an inherent property of the tRNA–codon interaction.

Preparation of Tri and Tetranucleotides and $\mathrm{tRNA}^{\mathrm{Met}}_{\mathrm{f}}$

Nucleoside diphosphates (NDP) of high specific activity were added to di and trinucleotides with primer dependent polynucleotide phosphorylase isolated from *Micrococcus luteus*[7]. Typical reaction conditions for the synthesis of a trimer XpYpN were: 0·1–1·0 mM ^{3}H-NDP (1–20 Ci/mmole, Schwartz), 6 mM XpY (Sigma), 10 mM $MgCl_2$, 0·4 M NaCl, 0·2 M glycine buffer (*p*H 9·3) and 0·3 mg/ml. polynucleotide phosphorylase. After 4 h at 34° C, the reaction was terminated by boiling and 0·1 mg/ml. alkaline phosphatase was added and reacted for an additional hour to degrade unreacted NDP. The products were separated from the reactants by descending paper chromatography as described by Thach[8]. Because the NDP concentration was much less than that of the primer, the major product was XpYpN, although smaller amounts of the tetramer, XpYpNpN, were also obtained. Usually 50 to 90 per cent of the NDP was incorporated into product molecules.

The synthesis of tetramers followed along similar lines: 0·1–0·3 mM NDP, 1 mM XpYpZ, 10 mM $MgCl_2$, 0·4 M NaCl, 0·2 M glycine buffer (*p*H 9·3) and 0·2 mg/ml. polynucleotide phosphorylase were reacted for 2 h to give 5 to 30 per cent of the NDP incorporated into XpYpZpN.

The $\mathrm{tRNA}^{\mathrm{Met}}_{\mathrm{f}}$ was provided by Oak Ridge National Laboratory, and has been assayed to have 100 per cent methionine and formyl accepting activity. The nucleotide sequence of *Escherichia coli* $\mathrm{tRNA}^{\mathrm{Met}}_{\mathrm{f}}$ has been recently elucidated[9].

Detection of Oligomer-tRNA Interaction

Dialysis was carried out in chambers made from a pair of 2·5 cm 'Plexiglas' acrylic plastic disks with a shallow cylindrical depression cut into each (1·8 × 12 mm). A membrane cut from dialysis tubing was placed between the disks to form two chambers each having a volume of about 200 µl. A narrow hole at the top of each disk allowed access to each side.

Experiments were carried out by loading a concentrated (80 µM) solution of tRNA on one side and 0·3–0·8 µCi of an oligomer on the other and allowing the system to come to equilibrium at 0° C. In 1·0 M NaCl, 10 mM $MgCl_2$ and 10 mM Na_2HPO_4 (*p*H 7·0), the buffer used in all these experiments, equilibration was reached in 24 h for trimers and 48 h for tetramers. After equilibrium, 3 µl. samples were withdrawn in triplicate from each side and counted.

If K is the association constant of an oligomer to a single complementary site on the tRNA molecule, and R is the ratio of oligomer counts in the chamber with the tRNA to the chamber without, then the relationship $R = 1 + K[\mathrm{RNA}]$ will hold as long as the molar RNA concentration greatly exceeds the molar oligomer concentration[10]. This requirement is met in these experiments because the RNA concentration is 40–80 µM and the oligomer concentration is 0·1–1·0 µM. (In these conditions the value of R is independent of the actual oligomer concentration, so that K values can be compared with oligomers of different specific activity.)

Interaction of Anticodon Loop with Oligomers

The association constants of the codon triplet, AUG, and a number of related oligomers with $\mathrm{tRNA}^{\mathrm{Met}}_{\mathrm{f}}$ at 0° C, are listed in Table 1. In interpreting these values it is important to note that association constants of less than about 250 correspond to R values, in the conditions of our experiments, of less than 1·02. Such values are taken to indicate no binding for the oligonucleotides used. It

† Present address: Harvard Medical School, Boston, Massachusetts.

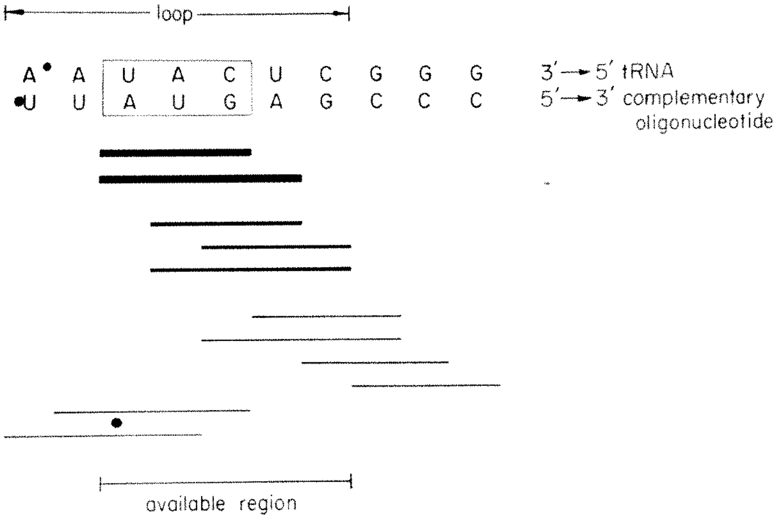

Fig. 1. The segment of *E. coli* fMet-tRNA investigated using complementary oligonucleotides. A heavy line indicates that the corresponding oligomer was bound; a thin line that it was not. A line of intermediate thickness indicates those oligomers whose binding constants were judged to be intermediate. The region of the anticodon loop found to be available for oligonucleotide binding is shown.

is likely that trinucleotides containing only A and U probably do have association constants in this range, but we have found it possible to avoid using this limited class.

Turning to Table 1, it is seen that the association constant for AUG is 1,200 l./mole. On the basis of association constants of other trimers[1] this value seems to be at the lower end of the range expected for trinucleotides containing only one G or C base. And because the complement, CAU, occurs only in the anticodon region of this RNA, it would appear that we are observing codon–anticodon association. Two sequence isomers were examined next: GAU and UAG. Neither was bound significantly. The complement to the first occurs once elsewhere but with one of its bases presumably in one of the helical regions. The complement of the other does not occur. Thus the lack of binding is understandable. The third sequence isomer, UGA, has an association constant of 400. This isomer has its complement in a triplet shifted one base from the anticodon; yet the *K* value is so low as to be ambiguous and is termed intermediate.

Table 1. MOLAR ASSOCIATION CONSTANTS OF OLIGOMERS WITH fMet-tRNA

Oligomer	*K*
AUG	1,200 ± 200
GAU	150
UAG	150
UGA	400
AUGA	13,500
AUGU	1,400
AUGC	900
AUGG	1,000

K was measured in 1·0 M NaCl, 10 mM $MgCl_2$, 10 mM sodium phosphate buffer (*p*H 7·0) at 0° C.

Table 2. MOLAR ASSOCIATION CONSTANTS OF OLIGOMERS WITH fMet-tRNA

Oligomer	*K*
UGA	400 ± 200
GAG	1,000
UGAG	2,600
AGC	150
GAGC	1,100
GCC	0
CCC	0
AUG	1,200
UAUG	1,100
UUAU	400

To examine whether or not the U on the 5′ side of the anticodon could participate in binding, the tetramer AUGA was synthesized and its binding measured. Similar tetramers with the other three bases at the 3′ end were also examined as controls. The results listed in Table 1 show clearly that this U in the anticodon loop can bind because the *K* value for AUGA is found to be quite high, 13,500. The other three tetramers display *K* values of about 1,000: this is similar to the association constant for AUG alone. Thus the specificity of the AUGA binding is emphasized by this order of magnitude increase in the value of *K* against no enhancement when the fourth base is non-complementary.

To complete the exploration of the availability of bases in the anticodon loop, a number of other complementary oligomers were made and their binding was measured. The results are listed in Table 2 and displayed in Fig. 1. It is seen that intermediate binding occurs at the second as well as the first base on the 5′ side of the anticodon; that is, GAG and UGAG bind with values that are significant but less than that expected when two G·C pairs are possible. But the following base, G, seems to be quite unavailable: GAGC binds about the same as GAG and AGC; GCC and CCC do not bind. Exploration of the availability of the bases on the 3′ side of the anticodon was limited to two oligomers, UAUG and UUAU. Because neither bound, it seems that both the first A and the second A to the 3′ side of the anticodon are not available for binding. It is most unlikely that they are paired with any other bases, so it follows that they must be held in a strained configuration incompatible with helix formation with a complementary oligomer.

The oligomer binding data summarized in Fig. 1 indicate that the sequence of five bases CUCAU in the anticodon loop are sufficiently single stranded to be able to bind complementary oligomers. The remainder of the loop, as well as the helical region proposed to close the loop, is not capable of binding oligomers. These data seem inconsistent with the model of the anticodon loop proposed by Fuller and Hodgson[11]. If the two A residues on the 3′ side of the anticodon are stacked with the anticodon along the same helix axis as the helix closing the loop, it would be expected that these A residues would be available for base pairing. Similarly, if the U and C residues on the 5′ side of the anticodon were strained, it would be expected that they would not be able to bind oligomers. Because we find that the A residues are not available to bind oligomers and the U and C residues are available but perhaps only after overcoming a minor restraint, it seems that some other conformation of the anticodon loop is correct.

The Wobble Interaction of GUG with $\text{tRNA}^{\text{Met}}_{\text{f}}$

In order to examine the possibility of a wobble interaction at the 3′ end of the anticodon, GUG and a number of related oligomers were presented to $\text{tRNA}^{\text{Met}}_{\text{f}}$ and their association constants were determined (Table 3). The association constant of GUG with $\text{tRNA}^{\text{Met}}_{\text{f}}$ was found to be the same as that of AUG. Further, GUGA has a much higher *K* than GUGU, suggesting that GUG is binding to the anticodon. This can be confirmed by performing competition experiments. If a large amount of non-radioactive AUG is included in a dialysis experiment, a sufficient number of anticodons are covered and the observed value of *K* for the radioactive triplet is

Table 3. MOLAR ASSOCIATION CONSTANTS OF OLIGOMERS WITH fMet-tRNA

Oligomer	*K*
GUG	1,200 ± 200
GUGU	1,000
GUGA	9,800
UUGU	400
AUG	1,200
AUG + 1·1 mM AUG*	500
GUG + 1·1 mM AUG*	600
GUG + 1·1 mM AAG*	1,100

* Non-radioactive oligomer.

decreased for that site. The results (Table 3) show that in conditions where the binding constant for labelled AUG is halved by unlabelled AUG, the observed value of K for GUG is similarly decreased. The presence of a similar amount of non-radioactive AAG does not, however, affect the value of K for GUG. We can therefore conclude that AUG and GUG bind to the same site on $\text{tRNA}^{\text{Met}}_{\text{f}}$.

Because the G·U bond at the 5′ position of the codon is only observed with $\text{tRNA}^{\text{Met}}_{\text{f}}$, it has been suggested that this is a reflexion of the special interaction of the initiator tRNA with the ribosome[12]. This possibility does not seem to be the case, for GUG will bind to the anticodon in the absence of ribosomes. The fact that no G·U bond was observed with the other U in the anticodon loop implies that the ability of the tRNA to form a particular wobble bond with the messenger RNA is a consequence of the structure of the tRNA loop and not of the environment supplied by the ribosome.

The technique of oligomer binding has proved useful in examining the detailed structure of a fairly well defined RNA loop. It should also be useful in exploring the conformation of the rest of the $\text{tRNA}^{\text{Met}}_{\text{f}}$ molecule as well as that of other RNA molecules of known sequence.

We appreciate helpful discussions with J. B. Lewis. This work was supported by a US National Science Foundation grant and the award of a National Institutes of Health predoctoral fellowship to O. C. U.

Derivation of the Secondary Structure of 5S RNA from its Binding of Complementary Oligonucleotides

by
JAMES B. LEWIS
PAUL DOTY
Department of Chemistry,
Harvard University,
Cambridge, Massachusetts

Using the oligonucleotide binding procedure outlined in the previous article, the secondary structure of 5S RNA has been explored. Most of the unpaired sequences have been identified, although the findings are not compatible with any of the published models of 5S RNA.

INCREASING knowledge of the sequences of various small RNA molecules has prompted much recent work on the secondary and tertiary structure of RNA. For the transfer RNAs it has been possible to arrive at plausible secondary structures by inspecting their sequences and pairing the Watson–Crick complementary regions into helices and thereby forming the familiar cloverleaf configuration[1,2]. Various physical and chemical studies support this result. But for 5S RNA, although sequences are known for that from *Escherichia coli*[3] and that from KB cells[4], no such uniquely plausible secondary structure is evident. A greater interest has therefore developed in the various physical and chemical techniques which may indicate the extent of base pairing in 5S RNA, although so far the clues provided have not been sufficient to provide a unique model of the secondary structure of 5S RNA. (As used here, a model of the secondary structure means a specification of which regions of the molecule are base paired in a double stranded fashion. The further folding of the molecule to give a three dimensional structure will be referred to as tertiary structure.)

Hypochromicity measurements of *E. coli* 5S RNA indicate that 60 per cent of the residues are base paired[5]. Ultraviolet difference spectra and optical rotatory dispersion suggest that the molecule is 67 to 82 per cent base paired, 60 to 70 per cent of these base pairs being G·C (ref. 6).

Other data suggest more specifically which regions are base paired. Certain regions of the 5S RNA molecule were found to be resistant to ribonuclease, suggesting that they were double stranded[3]. Oxidation with monoperphthalic acid indicated that only ten A residues are unpaired[7]. Most of the bases are inaccessible to carbodiimide, but the U residues in two particular sequences are more exposed and available for reaction[8].

Several of the secondary structures that have been proposed for *E. coli* 5S RNA (refs. 1, 3, 5, 9, 10) meet the approximate requirements imposed by the spectral studies, but they agree less well with the chemical and enzymatic analysis of secondary structure. Moreover, by contrast with tRNAs, the number of *a priori* plausible secondary structures having a proper percentage of bases paired is large[11] so that it seems impossible to propose a secondary structure of the molecule without additional knowledge of the specific sequences which are unpaired.

We wish to report the identification of most of the unpaired sequences in 5S RNA by determining whether or not complementary oligonucleotides bind to 5S RNA. The RNA molecule should only bind well those oligonucleotides whose Watson–Crick antisequences are unpaired in the molecule; it should show little affinity for those whose antisequences are base paired or otherwise inaccessible. By the use of many oligonucleotides, the entire length of the molecule can be mapped, overlapping oligonucleotides permitting an accurate assessment of the limits of the unpaired sequences. The technique employed is that used by Uhlenbeck, Baller and P. D.[12] to explore the structure of the anticodon loop in $\text{tRNA}^{\text{Met}}_{\text{f}}$.

On the basis of earlier work on the dependence of oligonucleotide interactions on base composition (O. C. Uhlenbeck, F. Martin and P. D., to be published) and the self consistency of the present results, one can readily decide if the observed value of the association constant K lies within the range expected if all bases are interacting with their complementary bases in the RNA; it is sufficient to restrict the oligonucleotides to trimers and tetramers. Within this narrow size range the value of K for binding to unpaired complementary regions at 0° C ranges from 400 to 400,000. Below 400 the binding is too small to be accurately measured. The variations within this thousand-fold range of *K* values are to be attributed to (*a*) the fraction of base pairs that are G·C, (*b*) the specific sequence and (*c*) the oligonucleotide length—three or four. Further, the conformation of the single stranded regions in the RNA may also influence the value of *K*. For example, an oligonucleotide may exhibit a different *K* value if it binds to the ends rather than to the middle of a looped out region. Additional problems may arise from the existence of denatured conformations of 5S RNA (ref. 13) inasmuch as the presence of small amounts of the denatured form could cause significant binding of an oligonucleotide the antisequence of which is not available in the native form. Our experience indicates, however, that all these effects are small compared with the three items listed above.

Of forty-one trinucleotides tested, twelve (including three controls the antisequences of which are not present in 5S RNA) did not bind ($K < 400$) and fifteen were judged to bind in the range expected. The remaining fourteen displayed some binding, but the *K* values were low and probably represented binding to a distorted region, to a small amount of denatured 5S RNA or to involve only a part of the sequence. The criterion for the binding of tetranucleotides was the finding of a value of *K* much larger (five to ten times) than the sum of the *K*'s of its two constituent trinucleotides. Of fifty-seven tetranucleotides tested, thirty-eight (including six controls the antisequences of which are not present in 5S RNA) did not bind and seven did; nineteen displayed intermediate values of *K*.

In these experiments, a *K* value of less than 400 is not experimentally different from no binding. Approximately half of the *K* values determined were done in duplicate. The duplicates displayed an average deviation from the mean of ±10 per cent for oligonucleotides with *K* values larger than 5,000, and ±25 per cent for oligonucleotides with smaller *K* values. For those trinucleotides capable of forming only one G·C bond, *K* values of 800 to 1,200 were observed. Those with more GC content had values between 2,000 and 5,000, except for those containing a GG sequence, in which case the constants were near 10,000 if the GG was at the 3′ end of the trinucleotide, and 20,000 or more if at the 5′ end. All the tetranucleotides observed to bind were capable of forming at least two G·C bonds, and had *K* values of greater than 30,000. If GG sequences were present, the *K* value was greater than 100,000. The association constants of a number of oligomers that illustrate these generalizations are displayed in Table 1. Examination of these results shows that the observed distribution of *K* cannot be explained as an artefact resulting from differences in composition and sequence of the oligonucleotides, but instead arises from the difference in accessibility of the antisequence on the RNA. Despite similar composition, three of the seven tetranucleotides have *K* values which clearly indicate binding as tetranucleotides; the other four can be explained by the binding only of their constituent trinucleotides.

Table 1. EFFECT OF BASE COMPOSITION ON *K*

Oligonucleotide	*K*	Classification
GUU	$0{\cdot}2 \times 10^3$	—
AUG	0·5	Intermediate
CAG	0·9	Intermediate
CUG	1·4	Intermediate
UGG	9·2	+
CGG	9·7	+
AGG	10·2	+
GGU	18·0	+
* GGC	61	+
AUGG	4·0	—
CUGG	12·2	—
CAGG	15·0	—
† GGUU	24	—
* AGGC	224	+
AGGU	139	+
* CGGC	423	+

* There seem to be two *E. coli* 5S RNA sequences, present in roughly equal amounts, differing in position 13 (ref. 2). One would expect a binding of 0·5 mole of AGGC and 1·5 moles of CGGC per mole of 5S RNA. Also, GGC probably binds at both positions 10–12 and 61–63. True molar *K*'s will accordingly differ from the observed *K*'s.

† Control whose antisequence is not present in 5S RNA.

To construct a map of secondary structure from these data, all of the antisequences of the oligonucleotides that did not bind well were underlined. Underlining a region once means only that at least one position is unavailable. If overlapping oligonucleotides are found not to bind, a region may be underlined several times, suggesting that most of the region is unavailable. Placing the oligonucleotides that did bind is less simple. The antisequences of some of the binding oligonucleotides are only contained once in the 5S RNA sequence. As much as possible, the other binding oligonucleotides are grouped around the six unique sequences to give the maximum overlap. The final result is summarized in Fig. 1, which shows four accessible regions ranging in size from four to eight nucleotides.

As an illustration of the method, consider the unpaired region nearest the 3′ end. The relevant binding data are listed in Table 2. It can be seen that the trinucleotides complementary to CAU and AUG bind very little, if at all, while the complement of UGC shows a small degree of binding. The complement to GCG binds, but the complement of CGA binds very weakly, and may be binding to positions 43–45. The complements of GAG and AGA do not bind. Further, the complement of CCAU does not bind, while the complements of CAUG and AUGC show

Fig. 1. Oligonucleotide binding to 5S RNA. All binding experiments were performed according to Uhlenbeck *et al.*[12]. The sequences underlined with dotted lines are those whose antisequences did not bind or bound very weakly. The sequences underlined with solid lines are the most probable sites for those oligonucleotides that did bind. The numbered brackets indicate those regions that may base pair. The 5S RNA used in these experiments was prepared by the method of Comb and Zehavi-Willner[14]. It was free of large rRNA and tRNA after chromatography on 'Sephadex *G*-100', using a 2·5 × 100 cm column with a flow rate of 2 ml./h/cm². The elution buffer was 0·1 M NaCl and 0·01 M potassium acetate (*p*H 7·0). 5S RNA exhibits several conformations, chromatographically separable on 'Sephadex *G*-100' (ref. 13). The material used here was not exposed to any conditions known to denature 5S RNA and eluted as one symmetrical peak from the column.

Table 2. MAPPING OF THE FOURTH LOOPED OUT REGION (... ^{93}CAUGCGAGA^{101} ...)

Oligonucleotide	5S RNA antisequence	K	K_{tri}*	Classification
AUG	CAU	0.5×10^3		Intermediate

CGC	GCG	2.6		+
UCG	CGA	1.4		Intermediate
CUC	GAG	0		−
UCU	AGA	0		−
AUGG	CCAU	4.0	9.7×10^3	−
CAUG	CAUG	4.4	0.8	Intermediate
GCAU	AUGC	9.0	1.3	Intermediate
CGCA	UGCG	34	3.6	+
UCGC	GCGA	4.8	4.0	−

* The sum of the K's of the two trinucleotides constituting the tetranucleotide.

intermediate binding. The complement of UGCG, which occurs only at this position in the 5S RNA sequence, definitely binds. The complement of GCGA does not. We conclude that the looped out region extends from position 93 to 98 or 99, although positions 93 and 94 are too distorted to bind oligonucleotides well.

An analysis of the base pairing possibilities of *E. coli* 5S RNA suggests that it may not have a unique secondary structure[11]. Our results indicate that there is at least one structure or perhaps several very similar structures that predominate. The four available, unpaired sequences that this work suggests are incompatible with all the published secondary structures for 5S RNA. Positions 9–11, 13, 27–31, 61–65 and 95 in Cantor's model; 9–13, 25, 28–32, 61–65 and 95–97 in Madison's; 9–13, 25 and 29–31 in Boedtker's model are said to be base paired, while these results show them to bind oligonucleotides. In addition, various oligonucleotides that would be expected to bind do not. One could say that a region predicted to be single stranded might be involved in further folding and thus not bind oligonucleotides, but it is difficult to visualize how a region predicted to be double stranded could bind oligonucleotides.

A possible base pairing scheme consistent with our results is presented in Fig. 1 by designating the most likely base paired regions. The two largest are both common to several of the secondary structures mentioned here[5,9]. The model can exist only in three dimensions, unlike the tRNA cloverleaf. There are no unpaired regions longer than three bases which were not found to bind oligonucleotides. Many of the oligonucleotides classified as intermediate can be considered to be binding at the distorted ends of the looped out regions. For example, GCC ($K = 1.4 \times 10^3$) and GAC ($K = 0.7 \times 10^3$) could be binding at the 5′ ends of the first and second looped out regions, respectively. UACG ($K = 15 \times 10^3$) could be binding at the 3′ ends of both first and third looped out regions.

In accordance with the spectral data[5,6], the model is 60 per cent base paired (counting four G·U bonds) and 64 per cent of the base pairs are G·C. One helix is interrupted by a looped out A residue. Of the twenty-four A residues, fourteen are unpaired, although not all of these fourteen are necessarily available for chemical reaction. The simple looped out A residues at positions 73 and 104 may not react to a reagent, such as monoperphthalic acid[7], in the same way as would an A residue in the middle of a larger unpaired region. The interpretation of the carbodiimide experiments[8] in terms of this model is less clear. The looped out regions proposed here provide several sites for the more reactive of the two reactive U bases. The less reactive U bases could only come from the melting of helical region 2 during the course of the reaction. Moreover, the model does not explain why several U residues available for oligonucleotide binding did not react with carbodiimide. Because the pairing pattern shown here requires the folding of the sequence in three dimensions, the tertiary structure thus imposed may sterically restrict the number of bases available for reaction with a given reagent.

This work was supported by a grant from the US National Institutes of Health, a US Public Health Service traineeship and a US National Science Foundation graduate fellowship. We appreciate useful suggestions and help from Dr Olke Uhlenbeck.

New Approach to Cancer

by

P. R. J. BURCH
MRC Environmental Radiation Unit,
Department of Medical Physics,
University of Leeds,
General Infirmary, Leeds

A unified theory of growth, cytodifferentiation and disease can explain many features of natural cancers which are incompatible with purely cytological explanations.

IN 1962, Smithers[1] published a vigorous challenge, "Cancer, an Attack on Cytologism". The following quotation conveys the essence of his thesis: "Cancer is a disease of organization, not a disease of cells; its field of study is the science of organismal organization; it cannot be encompassed simply by cytology"[1]. Smithers attacked the idea that a normal cell can be converted by a single, all or none, and irreversible process into "the cancer cell". In particular, he listed the following incompatibilities with cytologism. "(1) The multicentric origin of neoplasia. (2) The long prediagnostic natural history and the many predisposing factors in the development of tumours. (3) Age-incidence and geographical variations. (4) Progression and regression in tumour behaviour. (5) The conditional persistence of some tumours. (6) The hormone dependence of others"[1].

My collaborators and I have recently put forward a unified theory[2-7] of growth, cytodifferentiation and disease, and in this article I wish to show that it can account for those several features of neoplasia that, in Smithers' view[1], cannot be explained by "cytologism".

Outline of Unified Theory

We believe that, beyond a certain stage of embryogenesis, a central mesenchymal system regulates normal growth through a homoeostatic or feedback mechanism. In our view, many age-dependent diseases, including, perhaps, all natural malignancies, arise from a breakdown in the central part of the control system. The central control has two principal sections, corresponding to the anatomical division of target tissues between those on the blood side, and those behind, blood-tissue barriers. In the first section, one class of small lymphocyte (the kind involved in homograft rejection and delayed hypersensitivity) acts as the effector of symmetrical mitosis[2-4]. Humoral factors necessarily control symmetrical mitosis when the target tissue lies behind a blood-tissue barrier. Usually, these factors seem to migrate on electrophoresis with the α_2-globulin fraction: basophilic granulocytes and mast cells might be connected with their synthesis[3,5,6].

Effectors of symmetrical mitosis, which we call mitotic control proteins (MCPs), have to locate the correct target tissue, the cells of which are identified by tissue coding factors (TCFs). Tissue coding factors comprise histocompatibility antigens, tissue-specific antigens and subtler determinants that usually remain undetected in transplantation studies. Target cells secrete humoral TCFs which act as affector signals, and their rate of flow is proportional to the size of the target tissue. These affectors have to locate their cognate control element in the central system and inhibit the release of effector MCPs. Recognition, therefore, is a two-way problem.

We infer[2,3] that it can have only one genetic basis. The genes that code for some or all of the polypeptide components of a given MCP are identical with those that code for the corresponding polypeptide components of the cognate TCF[2,3]. When effector MCPs and affector TCFs are both humoral, they have to be distinguished: the difference resides in the non-protein components of the molecules, MCPs being complexed with carbohydrates, and TCFs chiefly with lipids[3].

A homoeostatic system of growth-control must contain a "comparator" to determine whether the target tissue has attained the correct size. We deduce that each growth-control element has its own comparator, which, from about the time of birth and onwards, consists of a fixed number of stem cells[2-7]. These cells are located principally or wholly in the bone marrow[3].

I have argued[3] that, in addition to their recognition function, TCFs also determine cytodifferentiation by derepressing, directly or indirectly, a particular set of genes. Specific cellular adhesiveness and the inhibition of mitosis produced by contact between similar neighbouring cells depend, we suggest, on the specific contact and self-recognition interactions between the TCFs of similar, adjacent cells[2,3].

Neoplastic Transformation in Autoaggressive Disease

Spontaneous autoaggressive disease of a tissue bearing a particular TCF is initiated by random gene mutations in a comparator stem cell of its central growth-control element[2-7]. Following Burnet[8,9], we believe that the mutant mesenchymal stem cell propagates a "forbidden clone" of similarly mutant descendant cells. "Mutant" MCPs attack the target tissue, the growth and size of which they usually regulate in their non-mutant form[2-7]. This attack results from a changed type of interaction. Whereas the protein components of the normal MCP bear an identity relationship to those of the TCF, the "mutant" MCP is complementary to the target TCF.

In the simplest form of carcinogenesis, "mutant" MCPs probably interact directly with target cells to transform them eventually into the neoplastic state[10]. Transformation probably entails a change in the structure of the TCF brought about by an induced change in gene expression. Invasiveness, and the destruction of normal by malignant tissue, result from strong interactions between the altered (mutant) TCFs in cancer cells and complementary TCFs in the cells of normal tissue.

Two kinds of experimental evidence support the idea that mutant MCPs change the structure of TCFs through an inductive mechanism. First, the influence of normal mesoderm on the differentiation of epithelia during embryogenesis is well established[11]. Only recently, however, has it been shown[12] that for some anatomical sites (ear, sole of foot, trunk) the normal dermis of the adult guinea-pig or hamster can determine the type of the overlying epidermis in recombinant grafts. Second, the lability of certain antigens on the surface of mammalian cells is revealed in the phenomenon of antigenic modulation[13]. The phenotype TL+, associated with certain mouse thymocytes, can be converted to TL− by the action of anti-TL antibody[13]. That the character of TCFs in target epithelial cells could be changed inductively by appropriately mutant humoral MCPs—which are somewhat analogous to classical antibodies—has therefore good precedents.

Evidence which I shall refer to later suggests that a target cell attacked by mutant MCPs might have to undergo one or more mitoses before neoplastic transformation is fixed. Even then, mitosis of the transformed cells is probably stimulated by, and during the first (pre-terminal) stage of cancer *in vivo* depends on, mutant MCPs.

In various non-carcinomatous malignancies, including Burkitt's lymphoma, Hodgkin's disease and certain leukaemias, proliferative change probably results from an indirect mechanism[3]. Here, the primary targets of the autoaggressive attack are likely to be processing cells that usually regulate the proliferation of lymphocytes or granulocytes[3,10]. The Reed-Sternberg cell is probably the altered target cell in Hodgkin's disease[3].

In certain types of leukaemia proliferating leucocytes probably come directly from a mutant growth-control stem cell[3].

Defence Mechanisms

Many chronic autoaggressive conditions can be exacerbated by specific infective agents[3,4]. Classical infectious diseases such as poliomyelitis develop only when the host is invaded by a particular type of microorganism. Nevertheless, the polio virus is not a sufficient cause. In an epidemic, a high proportion of the population produces anti-polio antibodies, but less than one per cent develops degenerative changes in the central nervous system.

I find that in populations which have not received prophylactic immunization, the sex distribution and age distributions of mumps, poliomyelitis and infectious hepatitis obey the same stochastic rules as those followed by idiopathic disorders[3]. This implies that the characteristic changes associated with these diseases develop in a person only if a forbidden clone has been recently initiated[3]. The average interval or latent period between the completion of initiation and the onset of symptoms is very short for these infectious diseases—some 0 to 6 months[3]. A combination of invading microorganisms and a recently formed forbidden-clone in the non-immunized person is essential to the expression of these infectious diseases.

Infective agents, of the appropriate specificity, probably precipitate pathological change by competing for immunoglobulin antibodies that would usually suppress the growth of a forbidden clone[3]. In chronic non-infectious diseases such competition increases the activity of the forbidden clone: the classical infectious diseases manifest only when microorganisms compete specifically for particular defence resources.

If the pathogenesis of cancers closely resembles that of non-neoplastic autoaggressive conditions, specific infective agents might sometimes play similar quantitative or qualitative parts in their development.

Relation of Unified Theory to Smithers's Critique

A unified theory of growth and age-dependent disease can call on a vast range of evidence for its support or refutation. For example, numerous observations relating to the multicentric origin of a non-malignant disease, clinical dental caries[3,7,15], become relevant to the understanding of the distribution of cancer foci. Indeed, two of Smithers's "incompatibilities with cytologism"—the multicentric origin and age-incidence—form the chief quantitative foundations of our theory[3–7,10].

Many stochastic models can account for the broad features of the age-patterns of cancer during adult life[3]. Sex distributions and age distributions for the range 0 to 20 years of age provide more exacting tests. When cohort changes or diagnostic error do not obtrude, the age patterns of numerous malignant and non-malignant diseases fit a simple biological model[3–7,10].

Our model postulates first that a specific autoaggressive disease can only arise in people genetically predisposed to it. Sometimes, as with osteoarthrosis, an entire community can be predisposed, but for other diseases such as Huntington's chorea, only a small fraction is genetically susceptible[3].

Second, a spontaneous autoaggressive disease is initiated in a predisposed person by a specific set of random gene mutations in growth-control stem cells. One or more mutations may occur in a single stem cell, or in multiple-stem-cells. The average rate of occurrence of each specific initiating mutation stays constant from about the time of birth to the onset of disease: it is unaffected by ordinary environments[3–7,10]. This constancy of rates during growth virtually eliminates biological models that would locate the initiating mutations in target cells. Most target tissues increase greatly in size between birth and maturity: the average rate of a particular somatic mutation in such tissues would increase with the growth in the number of cells. By locating the initiating mutations in the growth-control comparator, with its fixed number of cells, we can explain the constancy of mutation rates during growth.

According to our theory, the siting of neoplastic or degenerative foci depends on the anatomical distribution of target cells the TCFs of which are complementary to the mutant MCPs of the forbidden clone[3,7,15]. The simultaneous bilateral presentation of various tumours[16,17] can be understood readily in these terms.

I turn now to Smithers's second point concerning predisposing factors and prediagnostic signs. In our theory, the gene complement at fertilization determines predisposition. Inheritance is seldom simple autosomal dominant[3,18].

The progression from dysplasia, through carcinoma *in situ*, to invasive carcinoma of the cervix provides an outstanding example of prediagnostic signs[19]. Two distinctive groups of women (at least) are genetically predisposed to cervical cancer[10]. For the early-onset group with initiation-mode at about 45 yr (and, perhaps, for the late-onset group with initiation-mode at about 76 yr), four forbidden clones initiate the disease, and each stem cell requires three somatic mutations[10]. Probably one and/or two clones produce the early dysplasia, two and/or three induce carcinoma *in situ*, and four forbidden clones result in invasive carcinoma.

Hyperplasia precedes cancer of the breast which often presents unilaterally or bilaterally at many sites in the breast ducts[16]. Two groups of women (at least) are genetically predisposed to breast cancer and, in the early-onset group, three forbidden clones initiate the disease[10]. Probably, one and/or two of these clones promote hyperplasia.

Smithers's third point includes geographical variations of incidence. For spontaneous cancers, the principal factor in geographical variation is probably gene frequency, which determines the proportion of the community that is predisposed[3,10,20]. Changes of incidence with time also occur, and they often differ from one region to another. With the recent, and largely successful, conquest of the fatal infectious diseases, some of which are likely to be genetically associated (positively or negatively) with malignant diseases[3], we must now be living through a period of pronounced transition in gene frequencies. Cohort changes in the age-incidence of some cancers may well be the result of changing gene frequencies, produced by altered selection pressures. Should viruses prove to play an essential part in the pathogenesis of any cancer in man they could, of course, give rise to marked geographical and temporal variations of incidence.

The phenomena of progression, regression, conditional persistence and hormonal dependence—Smithers's points (4) to (6)—are commonly exhibited by many non-malignant autoaggressive diseases. In general, the course of a chronic disease will be determined by the balance or imbalance between the proliferative tendency of the forbidden clone and the restraining action of the endogenous defence mechanism[3,6,14]. Total remission, however, may follow from an appropriate mutation in the stem cell propagating a forbidden clone.

I suggest that the growth of many tumours before the terminal phase depends, at least in part, on mitotic stimuli produced by the interaction of mutant MCPs with their altered target cells. Such tumours will respond to fluctuations in the activity of forbidden clones. Steroids and adrenocorticotrophic hormone affect the balance between the defence and the level of mutant MCPs: they constitute the basis of many therapeutic measures. These and other hormones may also exert direct effects on the growth of certain tumours.

Laird[21,22] has found that in experimental animals, the growth of many primary and transplanted tumours follows a Gompertzian equation, to reach a limiting size. She concludes that a tumour grows . . . "as though it were a single organism, rather than a population of dissociated individual cells, each the progenitor of an independent line of tumour cells"[22]. These observations[21,22] suggest that the host controls the growth of a tumour, and of normal tissues, by similar mechanisms. The tumour grows disproportionately because the normal relation between the comparator and the target tissue has been altered.

It is commonly supposed that the persistent growth and invasiveness of a tumour and its metastases cause death. This view cannot easily be reconciled with the mathematical form of the survival curve, which can often be represented by a single negative exponential function ($S_\tau = \exp - \lambda\tau$), or by the sum of two such functions. S_τ is the fraction of patients surviving (corrected for mortality from other diseases) at time τ after diagnosis: the constant λ is characteristic of the type of tumour. This form of survival curve suggests that death might be precipitated by a single random event occurring during the post-diagnostic phase. From evidence that is too extensive to review here I believe that the "single random terminal event" may prove to be a somatic mutation in a cell of the forbidden clone that causes the cancer. This additionally mutant cell then propagates a new clone, which induces a fatal progression.

Chemical Carcinogenesis

The idea that random somatic mutations in stem cells of the central system of growth-control initiate spontaneous cancers seems to be contradicted by evidence for the local induction of tumours by carcinogens applied locally. When a small area of skin is treated with a chemical carcinogen such as 20-methylcholanthrene, skin tumours appear in the treated area. Such treatments cannot directly affect relevant growth-control stem cells in the bone marrow, and at first sight epidermal tumours might seem to result from the direct action of the chemical carcinogen on epidermal cells. Transplantation experiments[23,24] undermine this simple view. When pure epidermal- or thin Thiersch-grafts of skin treated with carcinogen are autotransplanted to untreated sites, no tumours develop in the graft skin[23,24]. A substantial yield of tumours can be obtained, however, when untreated epidermis is transplanted to a denuded area which had previously been treated with 20-methylcholanthrene. Thick Thiersch grafts and whole thickness grafts of treated skin yield a few tumours after autotransplantation. On the other hand, when whole thickness grafts of skin treated with carcinogen are re-implanted into the beds from which they have been cut, a larger yield of tumours arises more quickly than in unoperated controls[23,24].

These and other experiments suggest that direct action of the carcinogen on superficial epidermal cells *in vivo* cannot be responsible for their conversion to the cancerous state[23-25]. In our theory, a series of feedback loops connects the growth-control stem cells in the bone marrow to the final (peripheral) executive cells[2,3]. When the target tissue, such as the epidermis, lies behind a blood-tissue barrier, circumstantial evidence indicates that mast cells might in some cases act as the local executive cells of the central system of growth control[2,3].

The findings of Billingham *et al.*[23] described above agree with the idea that the carcinogen first induces mutations in growth-control cells in the dermis directly underlying the treated epidermis. (Recent observations[26,27] indicate, contrary to earlier suspicions, that hair follicles as such play no direct part in the production of tumours from the superficial epidermis.) Probably, the mutant peripheral growth-control cells then secrete mutant humoral MCPs which interact with overlying epithelial cells to produce carcinomatous transformation. To judge from the experiments with full thickness grafts, the effectiveness of this process depends, to some extent, on the proximity of the peripheral growth-control cells to the previous stage of the central system of growth-control—possibly neighbouring lymph nodes. When wounds—such as the removal and then restoration of a whole thickness graft—activate the growth-control mechanism locally to stimulate the secretion of mutant MCPs, the rate of tumour development is accelerated.

From electron microscope studies of the sequence of changes during the development of spontaneous and induced murine mammary tumours, Tarin[28] has argued that epithelial tumours may result from disturbed interactions between the epithelium and underlying connective tissue.

Radiation Carcinogenesis

Ionizing radiation delivered locally induces tumours in the irradiated area[29]. Nevertheless, dose-response relations[30-32] for the induction of certain dermal and epidermal tumours suggest[10] that the cells in which the initiating mutations are induced do not usually have to undergo cell division to produce a tumour. Again, mast cells in the dermis are possible candidates for the cells at direct mutational risk, and their secreted mutant MCPs might induce a neoplastic transformation in overlying viable epidermal cells.

This interpretation receives further support from experiments[33-35] designed to assess the depth beneath the surface of those cells that are at risk with respect to the induction of epithelial skin tumours. Glucksmann[33] reported that 0·3 MeV electrons failed to induce skin tumours in the mouse whereas 0·7 MeV electrons were effective. Albert *et al.*[34] found that protons penetrating 0·17 mm into the skin of rats did not induce tumours. From experiments with beams of electrons, these workers estimated that the cells at risk lie about 0·3 mm below the surface[34]. Although these workers suggest[34,35] that epithelial cells in hair follicles are the cells at carcinogenic risk, this attribution seems improbable in the light of other evidence[26,27]. Mast cells reside specifically in the radio-sensitive zone and their numbers show changes related to the course of chemical co-carcinogenesis and anti-carcinogenesis[36]. Riley[37] has already proposed that mast cells are involved in the "promotion" phase of chemical carcinogenesis.

Plastic Film Carcinogenesis

Many experiments have shown that target cells in tissue culture can be transformed into the malignant state by physical and chemical carcinogens and by oncogenic viruses. Cell replication is required to fix the transformed state of cells *in vitro* after injection of simian virus 40 (ref. 38). When cells are irradiated *in vitro*, two cell generations have to elapse before the transformed state becomes established[39]. Studies of the age-patterns of disease in man, on the other hand, offer no support for the idea that viruses contribute to the "initiation" phase of cancer or of non-malignant diseases[3,10].

All these observations can be reconciled if MCPs, normal or mutant, exert a controlling influence over the type of TCF that is synthesized by their cognate target cells. I propose that spontaneous mutations of TCF genes occur in target cells (probably "strand-switching" mutations[3]), but in ordinary circumstances do not lead to cancer, because certain of these mutations are reversed *in vivo* by an inductive interaction between the normal MCP and the mutant target cell.

An interpretation of plastic film carcinogenesis can now be offered. The presence of the physical barrier between cells reduces the area of cell to cell contact, diminishes the contact inhibition of cell division, and thereby promotes hyperplasia. This eliminates the need for cell division promoted by MCPs, and hence the monitoring role of the latter is also lost. Spontaneous strand-switching mutations of genes coding for TCFs in target cells become fixed through repeated cell division. Cells which have acquired the necessary complement of mutations propagate a cancer.

Value of Unified Theory

By locating initiating somatic mutations in central (mesenchymal) growth-control stem cells—instead of in cells of the target tissue that subsequently becomes neoplastic—we can readily explain those many awkward features of natural cancers in man that, in Smithers's view[1], dispose of earlier aetiological theories. Another advantage of our theory over earlier ideas is that it represents but one facet of a unified and consistent scheme of growth, cytodifferentiation and age-dependent diseases, both neoplastic and non-neoplastic. The theory incorporates the phenomenon of cancer into the general biology of multi-tissue organisms.

Should our synthesis prove to be substantially correct, new approaches to the problems of prophylaxis and therapy might be advantageous[3].

Gigantopithecus and the Origins of Hominidae

by
DAVID PILBEAM
Anthropology Department,
Yale University,
New Haven, Connecticut 06520

A re-examination of the available *Gigantopithecus* material has revealed that most of the supposed "man-like" characteristics of this fossil primate are not, in fact, hominid at all.

Gigantopithecus is an extinct man-like primate which has long been a puzzle to anthropologists and palaeontologists. The first species recorded, *G. blacki*, was discovered more than 30 years ago in Pleistocene deposits in China; recently, an older species of the same genus, *G. bilaspurensis*, has been located in Indian beds of middle Pliocene age. The exact taxonomic position of both species is controversial, and they have been variously interpreted as man-like apes, aberrant hominids or direct early human ancestors. An attempt is made in this article to outline the course of later Cenozoic hominoid evolution which culminated in the Chinese *Gigantopithecus*, to interpret the functional significance of the morphological trends in this lineage, and to review possible selective factors which might have produced these changes. This re-examination of the material reveals that most, if not all, the supposed "man-like" characters are not in fact resemblances to hominids at all, and that *Gigantopithecus* should not therefore be regarded as a hominid.

Records of *Gigantopithecus*

The first *Gigantopithecus* specimen was purchased in 1935 by Professor Ralph von Koenigswald in a Hong Kong drugstore[1]. This specimen, a right M_3, was chosen as the type of a new genus and species, *Gigantopithecus blacki*. Between 1935 and 1939, von Koenigswald purchased a further seven teeth of the same species. All eight teeth seemed to have come from Pleistocene deposits in southern China. Three of these were described by Weidenreich[2] in 1945. He concluded that *Gigantopithecus* was a gigantic ancestor of the middle Pleistocene hominid, *Homo erectus*. Von Koenigswald[3] described the eight teeth in 1952. He pointed out that the most reasonable age for the materials was middle Pleistocene and that they were therefore contemporaries of *Homo erectus*. He also concluded that, although *G. blacki* was a hominid, it was not ancestral to any later forms, being merely an extinct side-branch of Hominidae.

In late 1955 and early 1956 a survey team from the Academia Sinica located fifty more *Gigantopithecus* teeth in collections from caves in Kwangsi Province, southern China. In the summer of 1956 a mandible with most of the teeth preserved was discovered by a peasant in a cave in the same province, and in 1956 and 1958 two more mandibles, with much of their dentitions intact, came from the same cave. Between 1956 and 1960 more than a thousand isolated teeth were found in that cave and in others in Kwangsi Province.

After the discovery of this first jaw in 1956, Pei[4] published a short descriptive note in which he described *G. blacki* as an "ape", but from his discussion it is clear that he believed *Gigantopithecus* to be what would now be described as an aberrant hominid. In 1958, von Koenigswald[5] discussed all the material from China, which at that time consisted of two lower jaws and numerous isolated teeth. He concluded that *G. blacki* should be grouped with *Australopithecus* in a "pre-hominid" group, distinct from living and fossil pongids. The most complete account of *G. blacki*, including a description of all material known at the time, was published by Woo[6] in 1962. Like von Koenigswald, Woo concluded that *G. blacki* was a primitive hominid. In contrast, several other authors, including Simons and myself[7], and Remane[8], have treated *Gigantopithecus* as a rather peculiar, though nevertheless definite pongid.

The geological age of *G. blacki* is known only from a study of the associated faunal remains (there being no associated rocks suitable for radiometric dating) and is probably middle Pleistocene, perhaps around 0·5 to 0·75 million years old. That is, the samples are younger than *Australopithecus* in Africa, and of roughly the same age as the earliest *Homo erectus* finds in Asia and Africa. The associated faunas seem to include animals adapted to a number of different environments, including forest and woodland savannah[9].

The ancestry of *G. blacki* was conjectural until the recent description by Simons and Chopra[10] of a new species of the genus, *G. bilaspurensis*. This find, a mandible with almost all of the teeth still preserved, comes from beds of middle Pliocene age in Northwest India for which, unfortunately, there are no absolute dates. From studies of the associated faunas, the fossil can be given a probable age of between 5 and 9 million years[11]. These faunas also suggest that at this time north-west India was covered with grassland and relatively open woodland. Simons and Chopra[10] consider it likely that the "man-like" resemblances of the mandible are parallelisms, and that the *Gigantopithecus* finds are best considered as representing an independent line of apes. The basic morphological features of *G. bilaspurensis* are similar to those of *G. blacki*, although the earlier species was probably smaller, with lower-crowned and less cuspidate cheek teeth, and less markedly bicuspid front lower premolars.

Ancestry

The ancestry of *G. blacki* has been uncertain until now, although several authors have discussed possible ties with earlier forms. In 1952, von Koenigswald[3] very tentatively suggested a relationship with a pongid species that he had newly described as *Indopithecus giganteus* from late Miocene or early Pliocene beds in India and Pakistan. Simons[12] pointed to a possible link with the aberrant late Miocene hominoid *Oreopithecus*. With the recovery of *G. bilaspurensis*, some light can now be thrown on the ancestry of the Chinese form, because the Indian species is fairly clearly ancestral to, or close to the ancestry of, *G. blacki*. Because *G. bilaspurensis* is more primitive in a number of features, it is now much easier to look for possible ancestors among earlier Tertiary hominoids. These ancestors are probably to be located among Asian dryopithecines (primitive apes) of the Miocene and Pliocene.

There is one rather enigmatic specimen—a lower second or third molar—which may represent an early stage in the ancestry of *Gigantopithecus*. This tooth (Geological Survey of India specimen *D*175) comes from beds in West Pakistan; its probable age is early Pliocene, perhaps between 10 and 12 million years old, and it was associated with animals typical of forested environments. The specimen was first described in 1915 by Pilgrim[13] as *Dryopithecus giganteus*. Von Koenigswald later placed it in a new species and genus *Indopithecus giganteus*[14] (a conclusion with which Hooijer[15] disagreed). In 1965, Simons and myself[7] transferred this tooth to *Dryopithecus indicus*. It is a most interesting specimen, for although it is similar to *D. indicus* it is larger and narrower than other second or third lower molars of that species. In outline and in the general size, relative proportions, and disposition of the cusps, this tooth is very similar to *G. bilaspurensis*. Indeed, it is quite possible that *D*175 is sampled from a species ancestral to the entire *Gigantopithecus* lineage. The cusp morphology of *D*175 is, however, more primitive and resembles closely that of *Dryopithecus*. For this reason, it may be advisable to restore this tooth to Pilgrim's original species, *D. giganteus* (bearing in mind that it is generally poor taxonomic procedure to base new taxa on single teeth).

D. giganteus is similar enough to *D. indicus*[7] for it to be probable that the lineage leading to *G. blacki* evolved originally in Asia from a dryopithecine similar to (perhaps even identical with) *D. indicus*. *D. giganteus* is from the same horizons as *D. indicus*, although the latter occurs in earlier beds too. (A relatively complete lower dentition of *D. indicus* from early Pliocene beds in India will shortly be described by Simons and myself.) The lower molars and posterior premolar, in spite of having more sharply defined cusps, are very like *G. bilaspurensis* in outline, relative size of cusps, and so forth. The anterior lower premolar, although of fairly typical pongid sectorial form, nevertheless shows some features which foreshadow the premolars of *G. bilaspurensis*. I therefore propose the following as a tentative phylogenetic sequence: *Dryopithecus indicus* (late Miocene)→*D. giganteus* (early Pliocene)→*G. bilaspurensis* (middle Pliocene)→*G. blacki* (middle Pleistocene). This becomes, in my opinion, one of the best documented fossil ape lineages, extending through 10 or more million years. It is one, moreover, which shows a significant amount of morphological change.

Morphological Trends

The morphology of the molars in *D. giganteus* is of typical *Dryopithecus* form; the occlusal surface is rather restricted, and the cusps are conical. In *G. bilaspurensis*, cheek tooth cusps show much less relief and are flattened and plate-like rather than conical; occlusal surfaces are relatively broad and flat. *G. blacki* shows still further interesting changes; cheek teeth are higher crowned and also much more cuspidate.

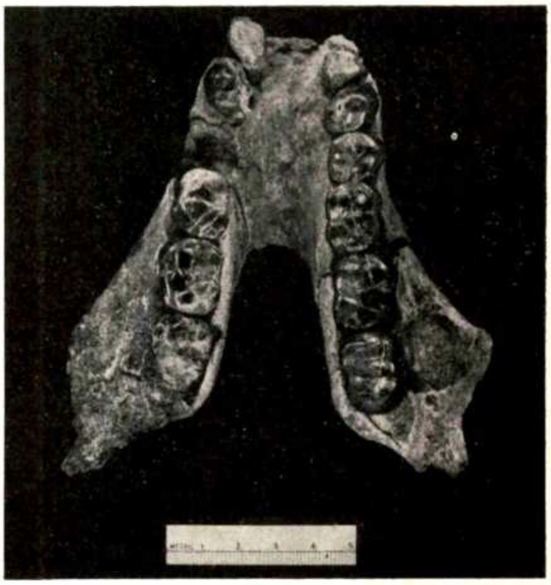

Fig. 1. *Gigantopithecus bilaspurensis* mandible from middle Pliocene beds in India.

The anterior lower premolar of *D. indicus* is an elongated, sectorial tooth. The principal external cusp is prominent, and although an internal cusp is usually present it is poorly developed. By the middle Pliocene the internal cusp was bigger, and the tooth was arranged in the mandible so that the long axis was oriented at less than 45 degrees to that of the other cheek teeth. In *G. blacki* the front premolar was even more clearly bicuspid; however, the trigonid was still quite well developed, suggesting that the upper canines sheared against the anterior face of the lower premolars. The cheek teeth of *Gigantopithecus* were packed closely together and showed considerable interstitial wear.

Canines were already relatively small in *G. bilaspurensis*. Even presumed males of *G. blacki* had canines which projected little beyond the plane of the cheek teeth. In both "males" and "females", the canines wore down rapidly on the tips, even at an early dental age. Both the upper and the lower canines were stout, broad teeth. Incisors were relatively small and closely packed between the canines. Relative to cheek tooth size, the incisors were smaller even than in the primitive dryopithecines of the Miocene and Pliocene. Between the Miocene and the Pleistocene there were trends therefore toward increased cheek tooth size, more molarized premolars, higher crowned and more cuspidate molars and premolars, smaller incisors, and reduced canines with occlusal surfaces more or less contiguous with those of the other cheek teeth.

Mandibular changes were equally marked. The mandibular body became very deep and robust in *Gigantopithecus*; the largest mandible of *G. blacki* is twice as deep as that of some male gorillas. The symphysis was strongly buttressed by superior and inferior transverse tori. The ascending rami originate opposite M_3 or the rear part of M_2, suggesting that the face was probably short; the gonial angles were thick and everted. Mandibular rami and tooth rows of *Gigantopithecus* diverged posteriorly, presumably because incisors and canines were small while the face was short relative to basicranial breadth.

Functional Interpretation of Morphology

How can these morphological trends and changes best be interpreted in functional terms ? One of the most distinctive and noticeable characteristics of both *Gigantopithecus* species is their large jaw size. Presumably these species had adult body sizes as large as or larger than modern gorillas: *G. blacki* was probably, on average, larger even than the mountain gorilla. This would suggest that they were creatures at least as terrestrial as the living African ape. Although ancestral *Dryopithecus* species seem to have been forest dwellers, *G. bilaspurensis* is found associated with an open country fauna[11], and one can probably infer a similar non-forested habitat for *G. blacki*[9]. It is likely therefore that *Gigantopithecus* species were adapted to foraging in relatively open country. None of the extant apes are so adapted ecologically, and for analogies among living primates it is necessary to turn to the ground-living Old World monkeys.

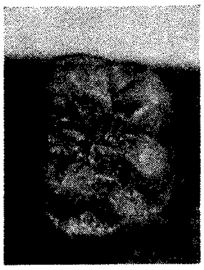

Fig. 2. Molar of a possible ancestor of *Gigantopithecus* from early Pliocene beds in Pakistan (*GSI D*175). Max. length: 18·3 mm.

Recently, Dr Clifford Jolly has shown[16] (and personal communication) that the dental, mandibular and facial adaptations of gelada baboons (*Theropithecus*) differ from those of other baboons (*Papio*) in features which can be correlated with differences in diet and manner of feeding. *Theropithecus* species, both living and extinct, have large cheek teeth coupled with small incisors, contrasting with the relatively larger front teeth of species of *Papio*[17]. Because of heavy use, gelada molars and premolars become packed close together and are heavily worn. Jolly relates the "*Theropithecus* complex", as he has called it, to the fact that these monkeys feed on small items—seeds, grass corms, and so forth—in large quantities. Such a diet requires large grinding cheek teeth and powerful masticatory muscles, while incisors are relatively unimportant. These features, and others, geladas share with the early hominids *Ramapithecus* and *Australopithecus*. Many components of the "*Theropithecus* complex" are also to be found in *Gigantopithecus*.

The small incisors of *Gigantopithecus*, fitting tightly between the canines, contrast markedly with the large cheek teeth. The molars and premolars were often closely packed and heavily worn. Premolars were molarized, so much so that the anterior lower premolar was fully bicuspid in *G. blacki*, thus increasing available chewing area. This was supplemented by what amounts to the functional incorporation of the canines into the posterior chewing battery. The canines of *G. blacki*, in particular, were small, stubby and broad. They became worn down rapidly from their tips, presumably as they erupted, so that they probably never actually projected beyond the other teeth. Although wear facets from upper canines can be observed on the P_3s of *Gigantopithecus*, these facets are only poorly developed. The canines of *Gigantopithecus* then became essentially grinding teeth additional to the premolars and molars. Thus it is important to note that although *Gigantopithecus* canines were reduced like those of Hominidae (and *Oreopithecus*), they were not incisiform slicing teeth like those of hominids. Functionally they were totally different, having become crushing rather than cutting teeth.

Numerous features of the mandible also point to powerful mastication. The symphysis was long, deep, and powerfully buttressed by large tori. These probably reduced anterior torsion during chewing, and Scott[18] has recently suggested a relationship between degree of development of such tori and the size of the masticatory muscles and cheek teeth. The horizontal mandibular rami were thick, deep and massively built; Vogel[19] believes that mandibles of this sort evolve in forms that are powerful masticators. The ascending rami turn upward quite sharply opposite M_2, and were probably set relatively vertically to the horizontal ramus. This would indicate that the face was also deep. Short deep faces—like those of *Theropithecus*, *Ramapithecus*, and *Australopithecus*—are adapted to powerful mastication. Chewing stresses can more readily be dissipated in a deep skull[20]. Masseters originating more anteriorly can exert greater power because their moment arm around the mandibular condyle is increased. That the masseters were powerful is also confirmed by the everted and buttressed mandibular gonial angles.

In conclusion, it is interesting to note the range of opinions concerning the status of *Gigantopithecus*, from the view that it is a true human ancestor to the idea that it was merely a man-like ape. I hope to have shown that, in phylogenetic terms, it was a pongid—although a peculiar one. If "traits" are simply listed, then "man-like" features are certainly to be found in *Gigantopithecus*: small incisors and canines, crowded and heavily worn cheek teeth, bicuspid front lower premolars, anteriorly convergent tooth rows, massive mandibles, and so forth. Viewed in functional perspective, however, it can be seen that these so-called "man-like" morphologies need not necessarily imply any relationship at all to Hominidae. Although the canines of *Gigantopithecus* were small like those Hominidae, morphologically and functionally they were very different. *Gigantopithecus* canines were large grinding teeth, not the chisel-like slicers of Hominidae. While it is true that bicuspid P_3s are typical of hominids, their presence in *Gigantopithecus* was probably the result of two factors. First, the reduction of the upper canines removed the necessity for an elongated P_3 to provide a blade-like shearing surface; second, the premolars became molarized because of selection pressures favouring more efficient mastication through increased tooth area. These two trends inevitably produced a bicuspid, barely sectorial P_3. The mere listing of such a trait has, in the case of *Gigantopithecus*, helped obscure the true relationships of that genus.

I thank Professor E. L. Simons, P. C. Ettel, Ian Tattersall and M. F. Gibbons, jun., for help during the preparation of this manuscript.

Teichoic Acids and Membrane Function in Bacteria

by
S. HEPTINSTALL

University of Newcastle upon Tyne, NE1 7RU

Selective destruction of teichoic acid reduces the ability of bacterial cell walls to bind Mg^{2+} ions.

ALTHOUGH studies relevant to the function of teichoic acids in bacteria are few, the widespread occurrence of these polyol phosphate polymers is evidence of their importance for the maintenance of cellular activity. Wall teichoic acids, including the structurally related polymers containing sugar 1-phosphate residues, are common among the Gram-positive bacteria[1] but are nevertheless absent from a number of species. In many of the species lacking wall teichoic acids, acidic polysaccharides possessing uronic acid residues are present in the walls, and it is likely that these polymers serve the same purpose. On the other hand, as far as reasonably extensive studies have shown, appreciable amounts of membrane teichoic acids are always present in Gram-positive bacteria. They occupy an ill-defined region[2] between the wall and the underlying cytoplasmic membrane; after mechanical disruption of cells of most organisms they sediment together with fragmented membrane[3], although they are sometimes absent from membranes prepared from protoplasts[2,4], thereby suggesting that the association with the cell membrane is loose or perhaps mesosomal. The walls and membranes of Gram-negative bacteria do not normally contain teichoic acids. They do, however, contain lipopolysaccharides which, like the teichoic acids, possess sugar residues, phosphate groups and basic residues, and which may serve a purpose similar to that of the teichoic acids.

The importance of these acidic macromolecular components in the outer regions of bacteria has been demonstrated experimentally[5] with *Bacillus subtilis*, where it has been shown that in continuous culture with phosphate limitation of growth, teichoic acid is no longer present in the walls, but in its place is found a polysaccharide containing uronic acid residues. The organism can presumably dispense with its wall teichoic acid provided that it can substitute another acidic polymer. It is especially noteworthy that even in the conditions of phosphate limitation of growth a membrane teichoic acid was found in the cells[6], suggesting a vital and indispensable role for this component.

It had been noted some time ago that, with the exception of the true halophiles, bacteria that are able to tolerate moderate concentrations of sodium chloride and other salts in the growth medium are relatively rich in wall teichoic acid, and the original suggestion[7] that these polymers might participate in ion-exchange and the control of access of ions to the inner regions of the cell has been strengthened and further developed by recent experiments. In particular it is likely that the ability[8] of isolated bacterial walls to bind cations, especially bivalent cations, has some bearing on the function of teichoic acids. It has been suggested[9] that this binding is the result of the presence of phosphate groups in the wall, and this work confirms that it is the phosphate groups of teichoic acids that are responsible for this effect; it is also shown that the amino groups in the alanine ester residues on the teichoic acid have a profound effect on cation binding, and this effect may be important in the proposed function of these polymers discussed here.

We have examined the walls of *Staphylococcus aureus* H and *Micrococcus* sp. 24 with respect to their ability to bind Mg^{2+}, and have studied the effect of removal of the alanine ester residues and of the teichoic acid. *S. aureus* H was grown in nutrient broth as previously described[10] and also in a medium of the same composition but containing 7·5 per cent NaCl; *Micrococcus* sp. 24 was grown in nutrient broth. Cells were disrupted with No. 11 'Ballotini' beads in a Braun cell disintegrator, and the walls were recovered by centrifugation and washed with 0·9 per cent sodium chloride and then water. The walls were heated at 100° C for 10 min in order to destroy autolytic enzymes, and then washed twice with a solution of 0·1 M EDTA at *p*H 6·8 and extensively with glass-distilled water and then freeze-dried. Atomic absorption spectroscopy after wet digestion[11] of the walls showed that the preparations did not contain detectable amounts of Mg^{2+}. Samples (25 mg) were suspended at 25° C in 50 mM sodium acetate buffer (10 ml.) containing 0·25 mmoles of $MgCl_2$ at *p*H 5·0, and portions were removed at intervals by centrifugation at 17,000*g*, washed four times with glass-distilled water to remove unbound cations and analysed for phosphate and Mg^{2+}. Alanine ester residues were removed from the teichoic acid in the walls by suspending a sample in 0·4 M hydroxylamine (salt-free) at *p*H 7·2 for 1 h at 45° C; earlier work has shown that in comparable conditions all alanine residues are converted to a mixture of alanine and its hydroxamate, and no detectable hydrolysis of phosphodiester linkages occurs[12]. Uptake of cations by many of the wall samples was complete after 30 min, but values quoted in Table 1 were determined after incubation for 16 h, when uptake was complete with all samples. During this time no alanine or organic phosphates were detected in the supernatant solutions.

Binding of Mg^{2+} Ions by Degraded Cell Walls

Walls prepared from *S. aureus* grown in standard conditions contained 0·59 moles of alanine ester for each phosphate. These walls bound 0·23 equivalent of magnesium for each phosphate (phosphodiester) group in the wall and after treatment with hydroxylamine this value rose to 0·56 equivalent. Thus removal of alanine results in a substantial increase in the ability of the wall to bind magnesium. Walls prepared from *S. aureus* grown in 7·5 per cent NaCl contained fewer alanine ester residues (0·20 mole/mole of phosphate) and bound a substantially greater amount of magnesium (Table 1). Removal of alanine from these walls also increased their magnesium binding capacity although to a lesser extent than was observed with walls that originally contained more alanine. Similar results were obtained (Table 1) for walls of the *Micrococcus* which contained 0·33 mole of alanine ester for each phosphate. These results show that the presence of alanine ester residues substantially affects the capacity of walls to bind magnesium, and it is possible that the alanine ester residues of the teichoic acid function in regulating surface charge and salt uptake.

Table 1. MAGNESIUM BINDING CAPACITY OF WALLS AND CHEMICALLY MODIFIED WALLS OF *Staphylococcus aureus* H AND *Micrococcus* SPECIES 24

	Alanine ester content of untreated walls (moles of ester alanine : mole of phosphate)	Magnesium content of wall samples (equivalents of magnesium : mole of phosphate)				
		Untreated walls	Walls after treatment with hydroxylamine	Walls after treatment with hydroxylamine and trypsin	Walls after treatment with 0·1 M sodium hydroxide	Walls after treatment with hydroxylamine and sodium periodate
Staphylococcus aureus H (grown in nutrient broth)	0·6	0·23	0·56	0·64	0·69	0·45
Staphylococcus aureus H (grown in nutrient broth containing 7·5 per cent NaCl)	0·2	0·51	0·79	0·86	0·82	0·65
Micrococcus sp. 24	0·33	0·55	0·79	0·87	0·84	0·86

Walls were incubated with magnesium chloride as described in the text. The resulting content of magnesium was determined by atomic absorption spectroscopy.

The wall samples from which alanine ester residues had been removed differed from each other in their binding capacity, suggesting that factors additional to the presence of alanine ester residues may moderate cation binding to some extent. Although this difference is not yet understood in detail, among the moderating factors appears to be the presence of protein. Thus after removal of alanine by suspension of walls in 0·1 M NaOH at 22° C for 60 min, the binding capacities (Table 1) were greater than those of walls that had been treated with hydroxylamine. Similar increases were observed after hydroxylamine treated walls had been incubated with trypsin (Table 1), and as it has been found that small amounts of protein are extracted from these walls by dilute alkali, the increased binding capacities are probably due to the removal of protein. Nevertheless, the binding capacities of walls from different organisms differed even after digestion with trypsin, so that further factors, possibly steric in nature, also influence the capacity of the phosphate groups to bind magnesium.

A direct demonstration that the phosphate groups are responsible for the cation binding was obtained by selective chemical removal of these groups from the wall. The phosphorus-containing component of the walls of *S. aureus* H is a ribitol teichoic acid possessing N-acetylglycosaminyl and alanine ester substituents[10]. Because the ribitol phosphate residues comprising the polymer chain are readily oxidized by periodate, this treatment will remove from the wall nearly all of the phosphate of the teichoic acid, leaving a small amount of phosphate associated with linkage between teichoic acid and peptidoglycan. On the other hand, the teichoic acid in the wall of the *Micrococcus*[13] possesses glycerol phosphate and N-acetylglucosamine 1-phosphate residues in its chain and is stable towards periodate. Because the peptidoglycan in both cases is stable towards periodate, the *Staphylococcus* can be used to study the effect on magnesium binding of selective removal of teichoic acid, and the *Micrococcus* represents an excellent control.

Periodate oxidation of walls was carried out by suspending them in 0·1 M sodium metaperiodate solution for 24 h at 21° C. Such oxidation of walls of *S. aureus* that had been grown in nutrient broth resulted in the removal of 75 per cent of the phosphate and a decrease of 80 per cent in the binding capacity of the residual wall material. Oxidation of walls prepared from cells grown in 7·5 per cent NaCl resulted in a loss of 92 per cent of the phosphate and 96 per cent of the binding capacity.

In contrast to the large loss in phosphorus and in magnesium binding capacity on oxidative removal of teichoic acid from the staphylococcal walls, the micrococcal wall was almost unaffected by periodate. Periodate treatment of untreated walls and of those that had had alanine ester residues removed yielded no soluble phosphates. The magnesium binding efficiency before removal of alanine ester was almost unchanged after the treatment with periodate.

The above results establish that the capacity of bacterial walls to bind bivalent cations is due to the presence in them of teichoic acids. Moreover, the binding capacity is greatly increased after removal of the alanine ester residues. It is proposed that a major function of both wall and membrane teichoic acids is to maintain a high concentration of bivalent cations in the region of the membrane. This is consistent with the cation binding properties of these polymers and its partial control through the amino groups of the alanine ester residues. It explains the observed structural diversity of teichoic acids and related polymers, for many structural varieties of polymers containing phosphate, amino and hydroxyl groups could satisfy the requirements for controlled cation binding. It also explains the vital requirement of cells for membrane teichoic acid; wall teichoic acids would be functionally less important and, although useful, could be substituted by other acidic polymers under unfavourable growth conditions. The superior importance of membrane teichoic acid is reflected in their much narrower structural diversity; thus all are glycerol phosphate polymers[1,14] and all possess D-alanine ester residues, the differences between them being confined to the type and number of glycosyl substituents.

In normal conditions of growth the most abundant bivalent cation would be Mg^{2+}, and the proposal that the major function of teichoic acids is to maintain a high bivalent cation concentration in the region of the membrane is supported by the observation[5] that organisms grown in a chemostat under conditions of Mg^{2+} limitation of growth possess exceptionally large amounts of wall teichoic acid. Presumably the teichoic acid content of the walls is raised in order to scavenge the limited supply of bivalent cations.

There are several reasons why it is important that the cell should be able to maintain a high concentration of bivalent cations in the region of its membrane. Many enzymes are bound to the membrane[15], including those required for the synthesis of membrane, wall and capsular components, for example, peptidoglycans, teichoic acids, capsular and wall polysaccharides, lipopolysaccharides, glycolipids and so on, as well as those required for electron transport and oxidative phosphorylation. The cation requirements of these enzymes have not been determined in all cases, but it is known that many require bivalent cations for optimal activity, and in some cases, for example, those for the synthesis of peptidoglycans[16,17] and teichoic acids[18,19], exceptionally high concentrations (20 mM or higher) of Mg^{2+} are required. The physical integrity of the membrane requires Mg^{2+}, as is shown in studies on the survival of protoplasts[20]. The association of ribosomes with the membrane during protein synthesis[21] also requires Mg^{2+}, as does the association of mesosomes with membrane[22].

Other Functions for Techoic Acids

Although we believe that the main function of teichoic acids is to provide the correct ionic environment for the membrane, this does not exclude the possibility that additional functions may exist in specific cases. Indeed, at least two cases of possible secondary functions are already known. In the *Pneumococcus* the dietary requirement for choline arises[23] through the presence of choline phosphate residues in the ribitol teichoic acid (C-substance)[24] in its wall. Ethanolamine can substitute for choline in the medium, and in these conditions ethanolamine residues are incorporated into the wall polymer. The effect of this structural change is dramatic[25]; reproduction is substantially unimpaired, but cell separation is inhibited and long chains of many hundreds of unseparated cells are formed. Moreover, the highly characteristic autolytic behaviour of old colonies of the organism is not shown by cultures grown with ethanolamine rather than choline. Although the mechanism of these changes has not yet been established, it appears that the effects are related to changes in the behaviour of lytic enzymes required for the process of separation of parent and daughter cells in cell division. In this connexion, the lytic properties of *Streptococcus zymogenes* are of interest[26]. This organism excretes enzymes into the medium which are powerfully lytic towards the walls of a number of other bacteria. Nevertheless, the walls of the *Streptococcus* itself are immune to attack. These walls possess a ribitol teichoic acid and, if the alanine ester residues are removed chemically, then the walls become sensitive towards the lytic enzymes. Again, the detailed mechanism of these effects is not yet established, but in both cases it seems that relatively small changes to the structure of wall teichoic acids, especially in the basic components, can have a large effect on the behaviour of lytic enzymes. As the cation requirement of these lytic enzymes has not been examined, it is not easy to decide whether these effects, caused by small changes in teichoic acid structure, are related to an independent secondary function of teichoic acids in controlling the activity of important lytic processes related to cell division, or whether the effects are again consequences of alteration in the cation balance which may cause changes in the activity of enzymes.

A further function of wall teichoic acids is associated with their charge. The demonstrable surface charge of bacteria is doubtless to be attributed in many cases to teichoic acid, and the maintenance of repulsive charges may be a desirable property enabling cell populations to disperse in the medium and thereby utilize nutrients efficiently. The effectiveness of this surface charge can be demonstrated with wall suspensions in buffers with constant ionic concentration but different *p*H values. At values below *p*H 7 the suspensions show a marked tendency to sediment. Moreover, walls that have had their teichoic acid removed by oxidation with periodate settle rapidly as a flocculent mass when attempts are made to suspend them in buffers over a wide range of *p*H.

We thank Miss Veronica Reid for assistance with atomic absorption spectroscopy. S. H. thanks the Science Research Council for a research studentship.

Plate Tectonics, Orogeny and Continental Growth

by

J. F. DEWEY

BBC, London

Ocean-driven plate mechanisms, the authors conclude, have been responsible for the growth and evolution of continents for at least 3×10^9 years. Some of the implications of this idea are discussed.

A GLOBAL tectonic mechanism in which essentially rigid lithosphere plates[1–4] are created at oceanic ridges, and consumed in oceanic trenches, provides a powerful framework for evaluating the development of orogenic belts and continents. Although continents are superficial passengers on moving plates, they place significant restraints[4] on plate evolution in that their buoyancy prevents their destruction by plate consumption. A variety of mountain, and continent, building mechanisms operate on leading plate margins as a result of the consumption of oceanic lithosphere. The plates of the present oceans probably contain no oceanic crust older than late Palaeozoic or early Mesozoic (personal communications from W. C. Pitman). It is therefore probable that the oceans suffer a complete turnover by plate accretion and consumption in about 250 m.y. The history of oceans before about 250 m.y. ago can only be elucidated by analysis of orogenic belts, in island arcs and continents, in which slices of oceanic crust (ophiolite suite) are preserved and mark the sites of former oceans. We take the view in this article that no kind of plate margin necessarily maintains a fixed position, that rates of plate production and consumption sum to approximately zero[5] on an Earth of essentially constant radius, and that lithosphere consumption only occurs on one side of a plate boundary. We consider below that the relationship of continents, island arcs and oceans has been determined by an ocean-based plate mechanism for at least 3×10^9 yr.

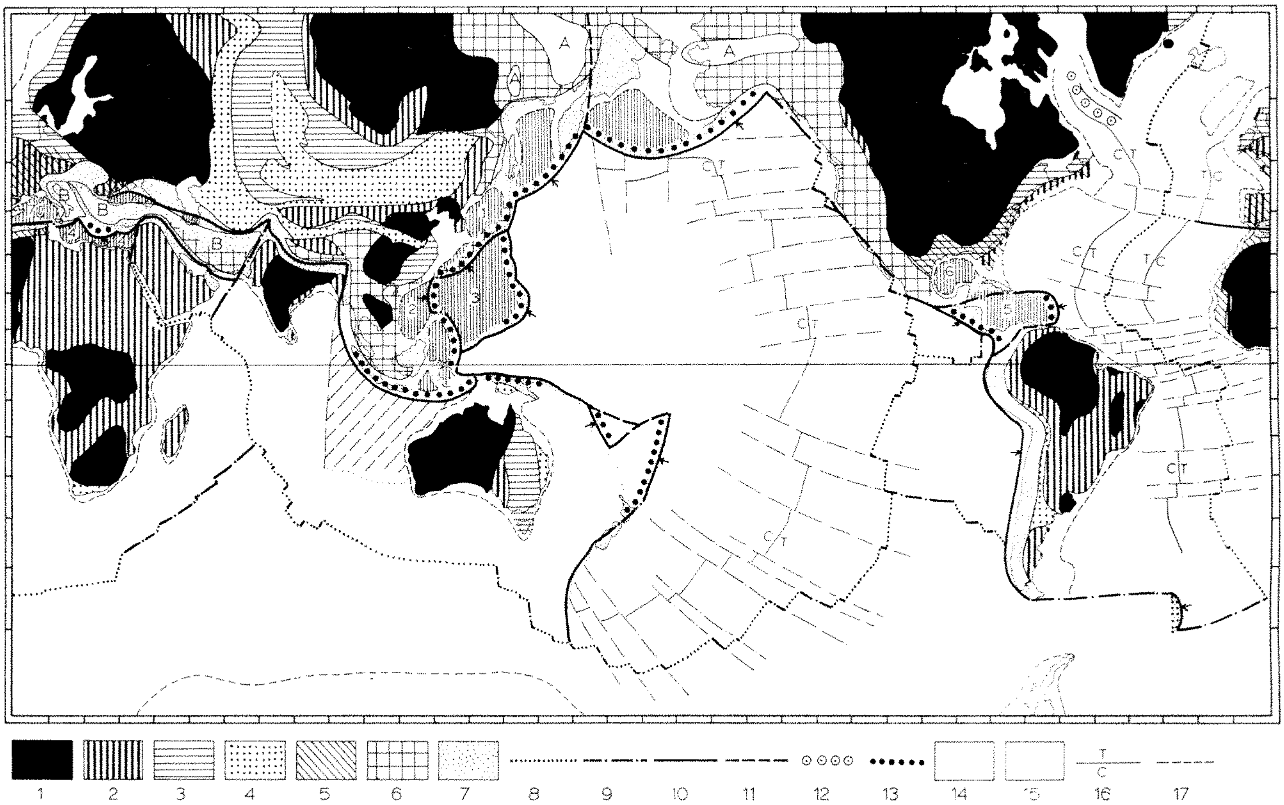

Fig. 1. Boundaries of present lithosphere plates and distribution of orogenic belts younger than 10^9 yr. Key: 1—Cratonic nuclei consolidated since 10^9 yr ago; 2—Late Pre-Cambrian (Baikalian) orogenic belts; 3—Lower Palaeozoic (Caledonian) orogenic belts; 4—Upper Palaeozoic (Uralian) orogenic belts; 5—Regions of Upper Palaeozoic regeneration (Alleghenian-Variscan); 6—Mesozoic (Cimmerian) orogens; 7—Tertiary-Quaternary (Alpine) orogens; 8—Accreting plate margins; 9—Transform plate margins; 10—Consuming plate margins (consuming side shown by small arrow); 11—Plate margins of indeterminate nature; 12—Extinct accreting plate margins; 13—Calc-alkaline vulcanicity; 14—Small ocean basins; 15—Remnants of Tethys; 16—Boundary of Cretaceous/Tertiary ocean floor; 17—Continental margins; A—Pre-Cambrian cratons of uncertain age; B—Internal microcontinents of the Alpine system of Europe and the Middle East. Latitude and longitude shown in 10° intervals.

Present Plate System

The Atlantic Ocean (Fig. 1) has been expanding in a varied and complex way since late Triassic times. The volume of sediments forming the continental rises depends on the rate of sediment discharge from adjacent continents from the time of continental separation. These continental margin sediments are largely non-volcanic and are thickest on the eastern margin of North America[6], reflecting accumulation since late Triassic times when Africa separated from North America. Elsewhere sediment volumes are smaller, reflecting separation of South America from Africa[7], Greenland and Europe from North America in Cretaceous times and Europe from Greenland in Palaeocene times. The result of the complex opening history of the Atlantic has been an exceedingly complex history of closure of Tethys now represented by remnant patches of ocean such as the Black, Caspian and Eastern Mediterranean Seas associated with the Alpine fold belt of Europe and the Middle East (unpublished results of J. Bonnin, J. F. Dewey, W. C. Pitman and W. B. F. Ryan). East of the Mediterranean further complexity arises from the growth of the Indian Ocean, whereby fragments of Gondwanaland such as India and Australia moved northwards to collide with Asia. The Indian Ocean thus consists of ocean developed from Cretaceous times with a much older Tethyan portion east of the Ninety East Ridge and west of Australia (Fig. 1).

In the Pacific, although lithosphere is being created at the East Pacific Rise and subsidiary ridges, it is being consumed in trenches at or near the Pacific Ocean margins. In western North America, the Mesozoic Cordilleran Orogen is bounded to the west by a ridge transform system argued[8] to be the result of driving the East Pacific Rise into a trench complex. In western South America, the Peru–Chile Trench precisely delineates the edge of the Mesozoic–Tertiary Andean Orogen on the continental margin. In the Western Pacific, however, plate consumption is occurring in trenches in front of island arc volcanic/orogenic belts within the ocean (Fig. 1). The simplest situation holds where, as in Japan, a small ocean basin lies between continental margin and island arc and the trench consumes the Pacific Plate. Further south there are complications. The Philippine Sea is a small contracting plate bounded by island arcs, pushing a finger westwards into, and therefore consuming part of, the South China Sea. The extending Fiji transform fault joins the New Hebrides Trench (consuming the northern Tasman Sea) to the Tonga Kermadec Trench (consuming the Pacific Plate). A range of present plate/ocean/continent combinations is shown in Fig. 2.

Evolution of Oceans

Lithosphere is being created by plate accretion along oceanic ridges in all the major oceans. In the Atlantic lithosphere consumption occurs in only two small regions (the Lesser Antilles and the Scotia Arc) and the continental margins are not plate margins. Because the Atlantic Ocean is therefore expanding, it is axiomatic that another major ocean is contracting. This is probably the Pacific, which has therefore to consume lithosphere at a rate that is the sum of its own rate of production and the rate of expanding oceans. The marginal Pacific trenches must therefore retreat into the ocean in front of continental margins and island arcs.

Although a pattern of linear oceanic expansion and contraction is an over-simplification, the effect of continental disruption, by plate growth, and convergence, by plate consumption, is that any continental margin will be the site of thick extensive sedimentation during continental separation and subsequently the site of orogeny during continental convergence[9]. This is the basis for our model of continental growth discussed below. In a sense this is an oceanic cycle but does not imply that the Atlantic, Pacific, Indian and Tethyan Oceans have all suffered alternate phases of expansion and contraction. There is evidence[10–12], however, that the Appalachian/Caledonian Orogen developed by contraction of a Proto-Atlantic Ocean roughly along the axis of subsequent opening of the central and northern Atlantic. Plate growth may begin along old lines of weakness and the effect of this will be a close association of orogenic belts of widely varying ages[13,14].

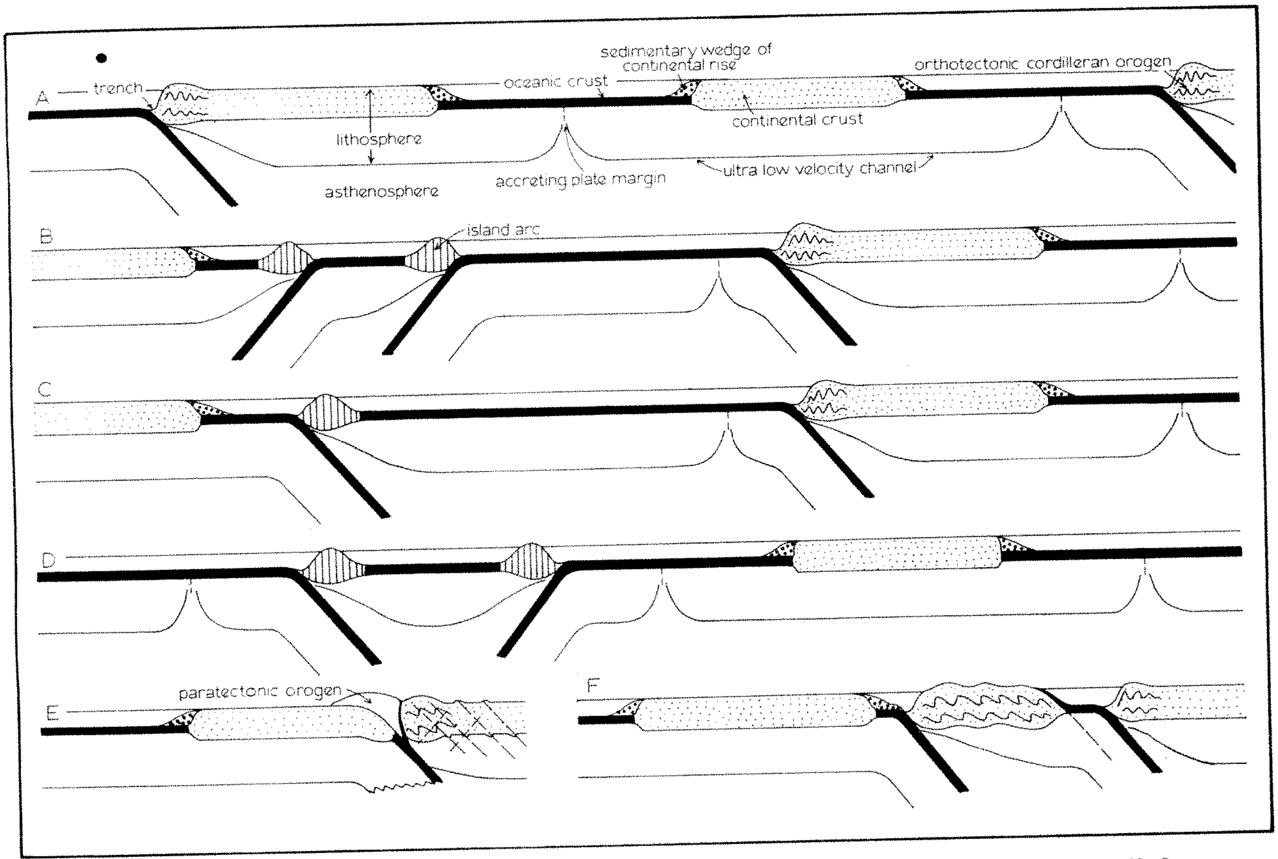

Fig. 2. Schematic relationships between lithosphere plates, continents, oceans, island arcs and orogenic belts. (A) Section from the Pacific Ocean, across South America, the Atlantic Ocean, Africa, and the Indian Ocean, to the Java Trench. (B) Section from South-East Asia, across the South China Sea, the Philippines, the Philippine Sea, the Marianas Arc, the Pacific Ocean, and South America, to the Atlantic Ocean. (C) Section from Australia, across the Tasman Sea, the New Hebrides Arc, the Pacific Ocean, and South America, to the Atlantic Ocean. (D) Section from the Pacific Ocean, across the Caribbean Sea, the Atlantic Ocean, and Africa, to the Indian Ocean. (E) Section from the Indian Ocean, across the Himalayas (site of lost Tethyan Ocean) to Tibet. (F) Section from the Atlantic Ocean, across Africa, the Eastern Mediterranean, Turkey, and the Black Sea, to the Caucasus.

A simplified view[9] of the present oceans is thus that they are either expanding (Atlantic) or contracting (Tethys). This is a grossly oversimplified way of analysing the behaviour of oceans because, although the Pacific is contracting, the oceans form a continuous system and cannot be considered separately. It is more accurate and instructive to consider the evolution of plates which may or may not carry continents as passengers. This emphasizes that the oceans and therefore plates are mutually interdependent and that continents may be disrupted and swept apart by plate motion, and may collide with island arcs or other continents. The great possible latitude and longitude changes involving continental separation and conjunction have fundamental implications for the distribution of animals and plants, particularly land-dwelling types. Faunal and floral province studies will contribute a great deal to our understanding of the relative positions of continents in the past.

Orogeny and Continental Accretion

The close spatial relationships of consuming plate margins, island arcs and the younger orogenic belts indicate with certainty that the energy source for mountain building is associated with plate consumption. Orogenic belts seem to be associated with both lithosphere consumption at continental margins (Andes) or in island arcs (Japan), and with continental collision (Himalayas). The conditions that determine the site and timing of plate consumption are so far obscure. It has been suggested[9,15] that an Atlantic-type continental margin with its thick pile of sediments on the margin of a wide old ocean, where the oceanic lithosphere is oldest and thickest, is eventually likely to become the site of lithosphere consumption and orogeny. Island arcs may be the result of the nucleation of trenches at microcontinents near continental margins. The onset of trench development may be related to the distance of a section of lithosphere from a ridge. If the lithosphere is regarded as a boundary conduction layer, steadily cooling and thickening away from the ridge, there may be a critical distance/thickness function at which time the plate sinks to form a trench. An alternative, or concurrent, possibility is that a major continental collision, after the closing of an ocean, resulting in cessation of plate consumption, leads to a situation where other active trenches cannot cope with lithosphere disposal and new trenches are forced to open, the likeliest positions being those already discussed.

There are at least four kinds of orogenic belt (Fig. 3) and the effectiveness of each type in accreting continents is discussed below.

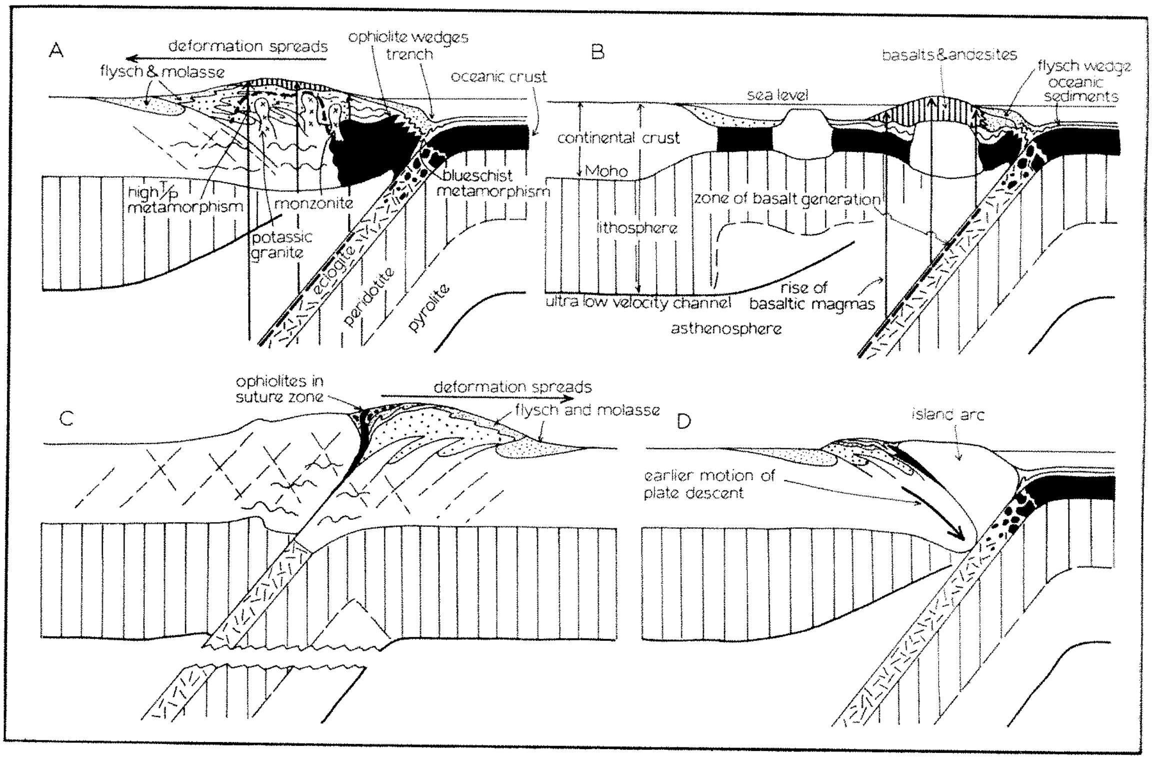

Fig. 3. Models for four basic types of orogenic belts developed at consuming plate margins. (*A*) Cordilleran-type orthotectonic orogen developed at the continental margin of a leading plate edge. The Mesozoic cordilleran orogen of the western United States is taken as the type example. (*B*) Island arc orthotectonic orogen developed on leading plate edge, perhaps nucleated on a microcontinent, within the ocean. (*C*) Himalayan-type paratectonic orogen developed by continental collision. (*D*) Paratectonic orogen developed by collision of a continent and island arc, followed by the development of a new consuming plate margin on the oceanic side of the arc. The Tertiary fold belt of New Guinea seems to have developed in this way. Southern New Guinea was part of the Australian continent and, after the contraction of an ocean (part of Tethys) between southern and northern New Guinea (Bismark island arc), collided with the Bismarck Island arc in Miocene times. A new trench then formed north of New Guinea to consume the Pacific Plate.

(1) *Cordilleran-type.* These develop at the continental margin of a leading plate edge when lithosphere consumption begins near the foot of a continental rise[9,13]. They are characterized by a deformation pattern (migrating towards the continent) developed by the contraction of the leading plate edge (Fig. 3*A*) weakened by the high heat-flow associated with the region behind the trench. On the inner wall of the trench, wedges of oceanic crust (ophiolite suite consisting of ultrabasic rocks overlain by basic intrusives and extrusives) are thrust up. These and the mélange of sediment scraped from the descending plate are deformed and metamorphosed in the high pressure, low temperature, regime of the blueschist facies. As the deformation spreads away from the trench, the sediments of the old continental rise are thrust, above basement wedges, on to the continent and affected by a high temperature metamorphism. Volcanics of the convergent tholeite-alkali basalt and calc-alkalic andesite suite are erupted and thus an orogen characterized by a paired metamorphic zonation is developed. The Jurassic/Cretaceous (Nevadan to Laramide) cordilleran orogen is believed to have developed in this way. The amount of lateral continental accretion achieved by a cordilleran orogeny may be quite small because, although continent-derived sediments are spread on to oceanic crust, the strip of oceanic crust trapped against the continent by the trench may be narrow and furthermore both this strip and the continental basement behind it probably suffer considerable contractions. The total width of an orogen such as the Cordilleras, the Andes, or the early Caledonides[11] cannot be considered to be a prism accreted during the orogeny. Only those parts underlain by ophiolite complexes may be taken as the accreted portion and the paucity of exposed ophiolites militates against an estimate.

(2) *Island arcs.* We suggest that island arcs are built when lithosphere consumption begins at some distance from the continental margin (Fig. 3*B*). Upthrusting of ophiolite wedges and the development of paired metamorphic belts occur[17] as in cordilleran orogeny. The crust of island arcs, perhaps nucleated on microcontinents, is built by the scraping up of oceanic sediments (of which chert is a significant component) and the accumulation of a thick pile of basalts and andesites and their acid derivatives[18]. Island arc development is an extremely effective mode for continental accretion. Not only is it a direct mechanism of building continental crust within an ocean, but the small ocean basins behind arcs are major sediment traps. The accumulation of a thick sedimentary sequence may convert a small ocean basin into continental crust, particularly as the high geothermal gradients[16] are likely to result in metamorphism.

(3) *Himalayan-type*. These are the result of the collision of an aseismic continental margin carrying a sedimentary wedge, against an opposing continental margin in the final stages of oceanic contraction. They are characteristically asymmetric and result from the squeezing of sediments which are heaped onto the continent of the underthrust plate (Fig. 3*C*). Upthrust wedges of oceanic crust (ophiolites) occurring in suture zones (for example, Indus Suture of the high Himalayas; Ivrea Zone of the Alps) are of great significance because these ophiolite belts represent the join-lines of collided continents. Underthrusting of a continent cannot proceed to any great degree because of buoyancy considerations and crushing and shortening begins to occur over a wide zone possibly following the detachment and sinking of the descending plate[4]. Himalayan-type orogeny works against continental accretion in that a small amount of continent may be underthrust.

(4) *New Guinea-type*. This type (Fig. 3*D*) results from the consumption of oceanic lithosphere on the continental side of an island arc, for example the consumption of the Tasman Sea on the west side of the New Hebrides arc. Eventually the continent carrying a marginal sedimentary wedge collides with, and partially underthrusts, the arc. Continued underthrusting is prevented by the buoyancy of the continent[4] and at this stage the descending slab is detached and a new trench is formed to consume lithosphere from the oceanic side. An island arc is thus accreted on to a continent. This notion of flip-over[4] in the direction of lithosphere underthrusting may be a partial explanation of why trenches are commonly associated with orogenic belts on continental margins. The trenches and island arcs develop within the ocean perhaps to be subsequently driven towards, and accumulate at, the continental margin.

Pre-Mesozoic Oceans

Plate tectonics will probably be used as a rigorous geometrical tool in working out the relationship between continents, orogenic belts and oceans well back into Mesozoic times. It will, however, only be valuable as a qualitative notion in understanding the relationships between older orogenic belts and long-vanished pre-Mesozoic oceans, unless large segments of transform faults like the San Andreas Fault are preserved and if palaeomagnetic isoclines are systematically deduced. If pre-Mesozoic orogenic belts were related to the evolution of the oceans, and the view that geosynclines are simply oceans and continental margins is accepted, detailed synthesis of sedimentary, igneous and metamorphic facies-assemblages in the older orogenic belts should yield valuable information for the evolution of the early oceans. This has been attempted for the Appalachian/Caledonian Orogen[10–12] where the geological history is consistent with this approach. The precise site of lithosphere consumption within the older orogens is likely to be represented by blueschist belts and ophiolite complexes. The ophiolites of the median suture of the Urals are associated with blueschist metamorphism and almost certainly lie on the site of a contracted ocean. The late pre-Cambrian (Mozambique–Damaran belts of Africa, Baikalian belt of Siberia, Fig. 1) orogens apparently present an obstacle to an oceanic origin in that large areas of these belts consist of regenerated earlier continental crust. The existence of earlier basement rocks beneath an orogenic belt, however, as argued above, does not imply a totally intra-continental origin, for during continental collision the ocean may be reduced to a narrow ophiolite bearing suture. A section across the Himalayas at a depth of 30 km might reveal a wide "regeneration" zone. Ophiolites occur along the edge of the Dahomey Belt in Ghana[19] but are rare in other African belts.

Within the oldest cratonic nuclei of Africa, such as the Rhodesian Craton, the mafic volcanic rocks and serpentine forming the lower parts (Sebakwian and Bulawayan) of the Schist Belt sequences[20] are overlain by more andesitic volcanics and coarse clastic sequences. It may be that the andesites and coarse clastic sediments represent island arcs built on a Sebakwian/Bulawayan ocean floor older than 3×10^9 yr. In the Yellowknife region of the Great Slave province of Canada tholeitic and calc-alkalic volcanics about $2{\cdot}6 \times 10^9$ yr old have been suggested to belong to an old island arc complex[21].

We submit, then, that ocean-driven plate mechanisms have been responsible for the growth and evolution of continents since at least 3×10^9 yr ago. During the early Pre-Cambrian, oceanic lithosphere plates perhaps considerably thinner and more numerous than at present controlled the growth of continental crust by the eruption of basalts and andesites and their acidic derivatives in island arc complexes. These were amalgamated by the moving plates until at some stage they formed small continental nuclei. We believe this process to be happening now, in a small scale way in the south-west Pacific, where the New Hebrides/Fiji/Tonga arc-transform system is building continental crust. Since the nuclei were formed, they were added to by the processes of accretion described here. During the early stages of continental growth island arc mechanisms must have been dominant, but as the nuclei enlarged they contributed increasing volumes of sediments to be spread on to the ocean floor as continental rises. Cordilleran accretion mechanisms have thus probably become progressively more important. This model of continental growth involving accretion on earlier nuclei does not imply a concentric accretion. The continuous evolution of oceans by plate growth and consumption leads to complex alternate phases of accretion on different margins of continents. As the continents grow and the oceans diminish in size, oceanic expansion–contraction cycles are likely to become more important. The cyclic opening and closing of oceans are inherent in the concept of plate tectonics because, if this were not the case, a single large continent would have been developed long ago. Continental accretion, however, may be exceedingly irregular, involving a continuous sequence of separation and amalgamation of continents, sometimes along old lines of earlier orogenic belts and sometimes across them to open new continent/ocean interfaces. Such terms as Gondwana, Laurasia and Pangea can therefore only properly be used to describe temporary conjunctions of continents.

Polarization of the Radio Pulses from the Crab Nebula Pulsar

We have undertaken a systematic investigation of the polarization of radio pulses from a number of pulsars, using a polarimeter feed in the Mark I radio telescope at 408 MHz. The results for the Crab Nebula pulsar, NP 0532, are of special interest, because they may be compared with the optical polarization recently measured by Wampler *et al.*[1]. We therefore now present a preliminary analysis for the main radio pulse, both in the form of an integration over many pulses and for individual pulses recorded photographically.

Our apparatus records independently the four Stokes parameters, presenting them either on a 4-channel oscilloscope, which displays individual pulses, or as integrated pulse profiles, giving the average over some thousands of pulses received over a period of several minutes. The pulsar NP 0532 is notoriously variable in that it occasionally produces an individual pulse very much larger than the average, so that about 1 in 10^4 pulses is photographable on the oscilloscope. We therefore arranged to trigger the oscilloscope only for large pulses; these were detected in a separate radio receiver tuned 2 MHz higher in frequency, so that the pulse arrived 12 ms earlier in the triggering channel, due to the interstellar dispersion in pulse arrival time.

Tracings of some of these photographs are shown in Fig. 1. All were recorded in the space of 10 min. The receiver bandwidth was 330 kHz (to 3 dB points), and the time constant of the detector was 0·5 ms. The pulses with apparent half-widths about 3·5 ms are therefore somewhat lengthened by dispersion in the receiver bandwidth, amounting to 2 ms. The polarization is predominantly linear, and totals about 70 per cent. It may be seen that the position angle of the plane of polarization of the largest pulse differs by more than 60° from those of the smaller pulses. With the present time resolution there is no conclusive evidence of fine structure in these pulses.

The shape of the integrated pulse profiles is very similar to that of the individual pulses, and also shows high polarization. At the peak of the pulse the ratio

$$\frac{(Q^2+U^2)^{\frac{1}{2}}}{I}=0{\cdot}65\pm0{\cdot}15$$

The plane of polarization does not rotate by more than 20° during the central 3 ms of the pulse, and does not change between successive 4-min integrations. The interpulse is less strongly polarized.

The high degree of polarization of the main pulse shows that the plane polarization does not contain much fine structure with time scale less than the present resolution, and further that the position angle variation from pulse to pulse is usually small. Other measurements made at 240 MHz with a time resolution of 3 ms show the same high degree of linear polarization.

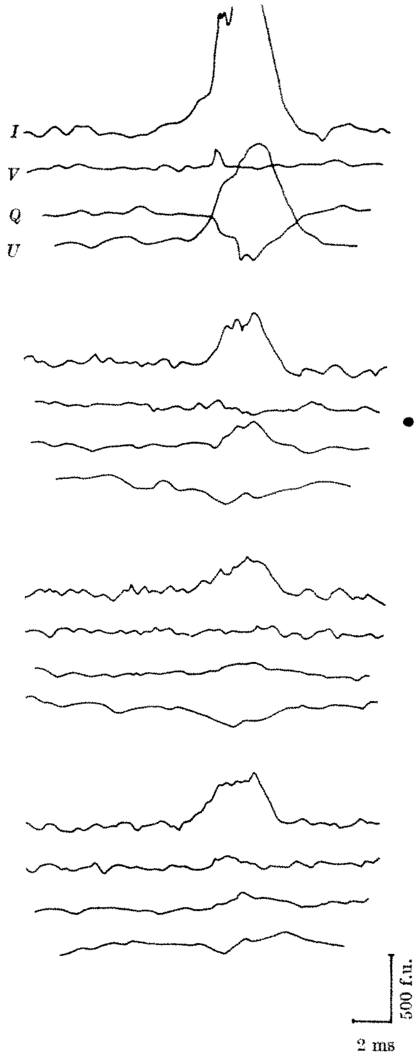

Fig. 1. Stokes parameters I, V, Q and U of four individual pulses from NP 0532.

These results are in sharp contrast to the optical measurements, which show only 10–15 per cent polarization, with a plane swinging through 120° during the centre 2 ms of the pulse. Wampler *et al.*[1] show that the optical results fit well with a simple geometrical model of the pulsar, in which the plane of polarization is determined by the orientation of two axes, a rotation axis and another related to the magnetic field. If the main radio and optical pulses are emitted simultaneously, then the model must evidently be revised. Observations at Arecibo, however (F. Drake, personal communication), have shown that the integrated profile of radio pulses observed at 408 MHz and lower frequencies shows a broad precursor pulse a few milliseconds before the sharp feature corresponding to the optical pulse. If our recordings refer to the precursor, it should be possible to describe the polarization angle as a continuous function through a considerable part of the pulsar cycle. We would then surmise that the sharp pulse and the precursor originate in different but adjacent regions.

Pulsar NP 0532: Average Polarization and Daily Variability at 430 MHz

MEASUREMENT of optical polarization has of course been limited to NP 0532. The optical radiation in both the main pulse and the interpulse, averaged over many pulses, is weakly linearly polarized (~15 per cent) with a position angle which rotates in a manner akin to that in PSR 0833–45 (refs. 1 and 2). The polarization properties, as well as the total intensity and pulse shape, seem to be time-dependent, however[3]. Circular polarization is absent.

With the single exception of PSR 0833–45, in an average over many pulses the polarized Stokes parameters tend to be reduced by the variability of pulsar polarization. It was therefore with some degree of temerity that we embarked on the measurement of the average Stokes parameters of NP 0532 at 430 MHz. Just to detect the pulsar in total intensity requires averaging over at least 10^4 pulses, and there are large fluctuations in the total intensity of individual pulses[4].

The observations were made with the 1,000-foot spherical reflector and 430 MHz line feed of the Arecibo Observatory. This feed provides two orthogonal senses of linear polarization, which are immediately combined to yield the two senses of circular polarization. These are then amplified, mixed to 30 MHz and transferred to the control building through coaxial cables.

Each sense of polarization was converted into two channels by mixing to baseband with a 30 MHz oscillator. The phase of the oscillator differed by $\pi/2$ for the two channels, so that the resulting voltage of the two channels at baseband differed in phase by $\pi/2$. Thus the four channels available at baseband consisted of the components $E_{\text{RH}}e^{i\omega t}$, $E_{\text{RH}}e^{i(\omega t+\pi/2)}$, $E_{\text{LH}}e^{i\omega t}$, $E_{\text{LH}}e^{i(\omega t+\pi/2)}$ where E_{RH} and E_{LH} denote the voltages available from the amplifiers on the two senses of right and left hand circular polarization. These four channels were passed through four identical filters which defined both the bandwidth and time constant; the bandwidth to 3-dB points was 8·2 kHz. The channels were simultaneously digitally sampled, recorded and later multiplied together[5] to provide the four Stokes parameters. For a total duration of 10 ms within each pulse period, samples were obtained at 5 μs intervals in windows centred on each pulse component. Samples were taken synchronously with the pulse period. The continuum emission from the Crab nebula itself was used as a calibration and to eliminate instrumental polarization; the source was assumed to be unpolarized.

Rotation of the feed during tracking was accounted for. The Faraday rotation due to the ionosphere was measured approximately using the critical frequency from the ionosonde at the Arecibo Observatory in conjunction with approximate profiles of ionospheric density kindly supplied by G. Nelson. The critical frequency was measured continually during our observations, and the Faraday rotation, which varied from about 13° to 26°, was accounted for.

Observations were made for two or three hours on October 26 and 27 and November 1 and 3, 1969. Unfortunately, the lengths of cables in the systems were changed before we were able to fix the directions to which the linearly polarized Stokes parameter refer. We cannot therefore specify the position angle of linearly polarized radiation.

Fig. 1 shows the four Stokes parameters, averaged over 757,600 pulses. The individual data points, whose separation is 50 μs and which are nearly independent, have been smoothed by 200 μs to increase signal/noise—no significant short time scale structure was present in any Stokes parameter before smoothing. It is immediately evident that there is a high degree of linear polarization whose position angle must be independent of time because one of the linear Stokes parameters is zero. This point was also clear on the original data, and therefore the direction of the reference system was rotated so that all of the polarized power appeared in one Stokes parameter, for the sole purpose of clarification in presentation.

Fig. 1 also shows the fractional linear polarization. This is normally defined as $(Q^2+U^2)^{1/2}/I$, but because all of the polarized power appears in only one Stokes parameter, the fractional polarization given in Fig. 1 was computed simply as Q/I.

We examined the results averaged over each day of observation. Although the small signal to noise ratio prohibited seeing variation of the polarized Stokes parameters (Q, U and V) from day to day, it was clear that the total intensity, I, was variable from day to day in some of the pulse components. We emphasize that our measurements of the Stokes parameters are in terms of the intensity of the Crab Nebula, which was responsible for 89 per cent of the system noise, and that our detector has a perfect square law because detection was done digitally. The flux, S, in each of the three components was obtained for each of the four days by integrating over the appropriate phase intervals within the pulse period (see Fig. 1) and are given in Fig. 2.

Fig. 1 confirms the existence of three components in the pulse period (unpublished work of Rankin *et al.*). From Fig. 1 we infer (errors quoted are maximum errors derived from the peak to peak noise level in the baselines of Fig. 1): (*a*) The precursor is essentially 100 per cent linearly polarized over most of its width and the variations are consistent with the noise levels in Q and I. The main pulse is about 18 per cent linearly polarized during its rise and at its peak and more highly polarized during its decay. The polarization of the interpulse is very weak indeed, less than 11 per cent at its peak. The fractional polarization increases near the final stages of both the main pulse and the interpulse, but this could easily result from the noise levels in Q and I. (*b*) The position angles of the precursor and the main pulse are the same, and the angles do not rotate within either pulse. Noise fluctuations in Q and U allow random variations of about ±20°. Systematic variation of the position angle within each pulse is much less. (*c*) The fractional circular polarization, V/I, is less than about 25, 8 and 10 per cent for the precursor, main pulse and interpulse respectively.

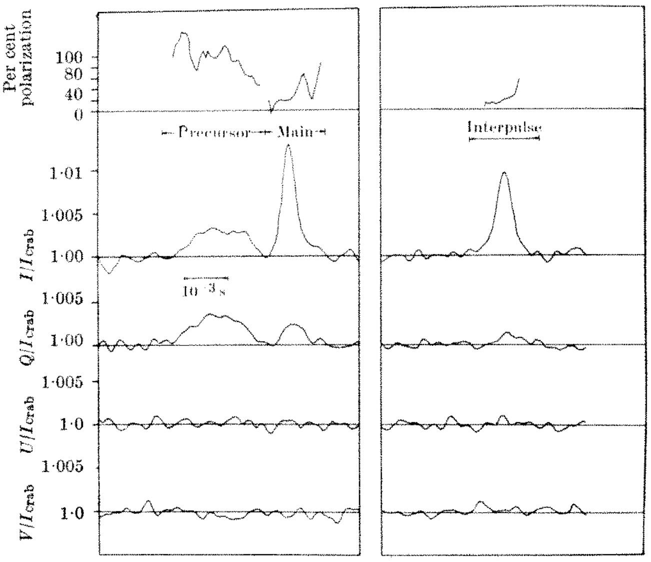

Fig. 1. From the top down: fractional linear polarization Q/I, in per cent; the total intensity Stokes parameter, I; a linearly polarized Stokes parameter, Q; the other linearly polarized Stokes parameter, U; the circularly polarized Stokes parameter, V. All Stokes parameters are in terms of the total intensity. Stokes parameter of the Crab Nebula radio source, I_{crab}.

Of course the high fractional linear polarization of the precursor itself implies little fractional circular polarization. (*d*) The polarization properties of the precursor must be constant from pulse to pulse, because the average polarized power in one of the linear Stokes parameters is essentially equal to the total intensity.

Our results for the main pulse and for the interpulse are somewhat affected by the measurement process. Our bandwidth of 8·2 kHz yields a time resolution of halfwidth about 120 μs because of interstellar dispersion and filter rise time. The halfwidth of the main pulse without the 200 μs smoothing in Fig. 1, not shown here, is about 250 μs. Thus instrumental broadening is not completely negligible, and variations of the Stokes parameters within the pulses are integrated over to some extent. If the position angle rotates by about 90°, as it does for PSR 0833–45, the average value of the Stokes parameter, *U*, across the pulse in Fig. 1 would be nearly zero; instrumental broadening would make it difficult to detect.

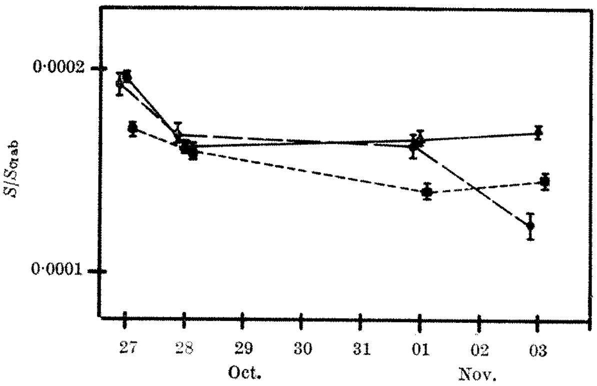

Fig. 2. Flux of the three pulse components averaged over the observing period of each day, in units of the flux of the Crab Nebula radio source, S_{Crab}. Errors shown are probable errors. ● – – – ●, Precursor; ▲—▲, main pulse; ■ - - - ■, interpulse.

The lack of rotation of the angle of rotation in the precursor, however, must be genuine, because the precursor does not suffer from inadequate time resolution. This constancy is in marked contrast to previous results and to the currently accepted view that the rotation is a general phenomenon. Given the picture of Radhakrishnan and Cooke[6] that the neutron star emits only in a cone centred on the magnetic axis, the lack of rotation of the polarization angle implies that the magnetic axis and line of sight to the Earth are instantaneously very closely aligned as the neutron star rotates. This implies that the precursor–mainpulse combination is associated with one magnetic pole and the interpulse with the other, and therefore that the magnetic axis is close to perpendicular to the rotation axis. The low probability of such a favourable alignment in the most prominent supernovae remnant perhaps casts some doubt on this theory.

The linear polarization of the precursor must be responsible, in large part, for the variation of its intensity found by Rankin *et al.*, who observed only one sense of linear polarization. They used a telescope with an alt-az tracking system and observed during the daytime when ionospheric Faraday rotation is large and variable. These effects would cause the essentially completely linearly polarized precursor both to vary its apparent intensity and to appear weaker, on the average, than it really is. Not all of its observed variation can be ascribed to polarization, however.

The total flux, *S*, of each pulse component was calculated by integrating the Stokes parameter, *I*, over time (Fig. 2). Of course, polarization cannot affect these results. The variations of the precursor and main pulse are much larger than the errors, while the flux of the interpulse varies somewhat less. There is no obvious correlation.

The physical cause for the variations must lie in the pulsar itself rather than in interstellar scintillation, because scintillation would be expected to affect all three components equally. Unfortunately, the Crab Nebula generates too much noise to examine the flux behaviour in our data on a time scale less than one day. But the large fluctuations in pulse intensity, which facilitated the discovery of NP 0532, show that variations exist on shorter time scales too—time scales which may include the range usually associated with interstellar scintillation. Variations on such time scales are found at optical wavelengths[3], but we in no sense imply any association whatsoever between the emission processes in the radio and optical, in view of the differences in pulse structure and polarization for the two wavelength regions. Other pulsars may have similar intrinsic variations; it is the multiple pulse structure of NP 0532 which allows us to conclude that scintillation does not play a part.

We thank D. W. Richards for discussions and J. Comella for assistance. The Arecibo Observatory is operated by Cornell University under contract to the US National Science Foundation and with partial support from the Advanced Research Projects Agency. This work was supported in part by the US Air Force Office of Scientific Research. One of us (J. M. Size and Motion of the Interstellar Scintillation Pattern from Observations of CP 1133

THE time variations of the intensity of pulsar radiation at radio frequencies may be described by the superposition of short and long term fluctuations. Scheuer[1] has shown that the short term fluctuations are most probably intrinsic to the source, and both Scheuer and Salpeter[2] have suggested that the long term fluctuations may be scintillation caused by irregularities in the interstellar medium. B. J. R. (ref. 3 and unpublished work) provided some evidence for the interstellar scintillation hypothesis when he observed a correlation between dispersion measure and the characteristic bandwidth over which the intensity variations are correlated. Additional evidence has been provided by Lang[4], who has shown that the long term variations of four pulsars have power spectra, modulation indices, frequency distributions and decorrelation frequencies which are consistent with the predictions of scintillation theory.

The simplest theory of the scintillations relies on the assumption that the motion of the pulsar and/or the interstellar medium with respect to the Earth causes a stable diffraction pattern to be swept past a single antenna. We have observed the fluctuations of pulsar intensity with spaced antennae in an attempt to measure the scale size and motion of this diffraction pattern. In general, the fluctuations may be both partially decorrelated and also show a time shift between the two sites. The maximum cross-correlation coefficient and its associated time delay then give some information about the apparent scale size and velocity of the pattern, respectively.

The pulsar CP 1133 was observed for simultaneous three hour periods at Arecibo and Jodrell Bank on June 20 and 22, 1969. Observations were made with right hand circularly polarized antennae connected to radiometers centred at 406·0 MHz with bandwidths of 500 kHz and time constants of 10 ms.

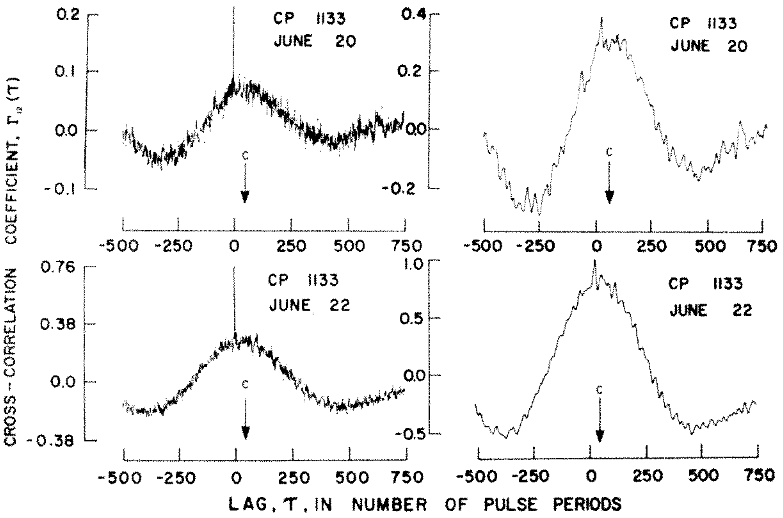

Fig. 2. Cross-correlations of pulse intensities detected at Arecibo and Jodrell Bank (left side). The right side shows cross-correlations between pulse intensities smoothed by taking running means over ten pulses. The centroid of the cross-correlation function is denoted by the letter C.

Pulse intensities (ON intensities) were calculated by integrating the power within windows of data which were 100 ms wide and which were centred in each pulse. Intensities due to system noise (OFF intensities) were similarly calculated for windows centred midway between pulses. The ON intensities were smoother by running means over ten data points, and the autocorrelation function, $\Gamma_{11}(\tau)$, was formed from the smoother intensities of each observation (Fig. 1). The correlation function $\Gamma_{12}(\tau)$ of the intensities $I_1(t)$ and $I_2(t)$ recorded at time t by radiometers 1 and 2 is defined as

$$\Gamma_{12}(\tau) = <[I_1(t) - <I_1(t)>][I_2(t+\tau) - <I_2(t+\tau)>]>/\sigma_1\sigma_2 \qquad (1)$$

where < > denotes a time average and σ_1^2 and σ_2^2 are the mean square deviations of $I_1(t)$ and $I_2(t)$ respectively. Also shown in Fig. 1 are the modulation indices, M, defined by

$$M = \{[(\sigma_{\mathrm{ON}})^2 - (\sigma_{\mathrm{OFF}})^2]/[<I_{\mathrm{ON}}(t)> - <I_{\mathrm{OFF}}(t)>]^2\}^{1/2} \qquad (2)$$

The autocorrelation functions and the modulation indices observed at the two observatories are nearly identical when the effects of noise are taken into account.

The cross-correlation function, $\Gamma_{12}(\tau)$, was formed from the ON intensities recorded at the two observatories (Fig. 2). These ON intensities were then smoothed by running means over ten data points, and the cross-correlation of the smoothed data is also shown in Fig. 2. The abscissae are defined so that a positive lag corresponds to a pulse group arriving at Arecibo after it arrives at Jodrell Bank. The observed decorrelation is thought to be the result of noise. The narrow spike at zero lag is a result of the short term fluctuations in the radiation intensity. This spike is an additional indication that short term fluctuations are intrinsic to the pulsars.

The peak value of the smoothed cross-correlation functions, $\Gamma_{12}(\tau)$, when corrected for the noise contribution to

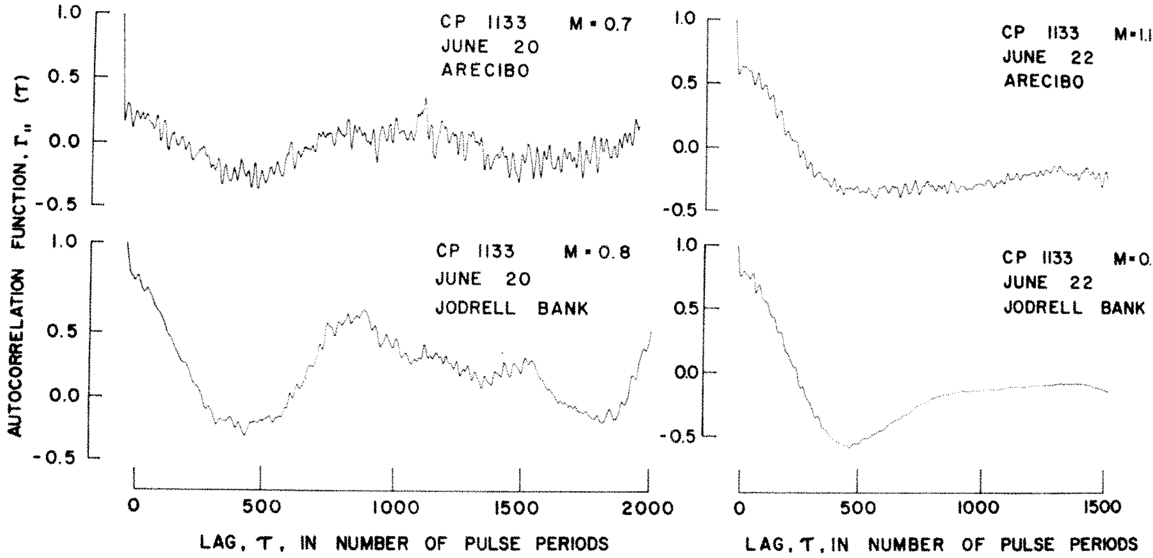

Fig. 1. Autocorrelation functions of smoothed pulse intensities detected at Arecibo and Jodrell Bank on two different days. The pulse intensities were smoothed by taking running means over ten pulses.

σ_1 and σ_2, are not significantly different from unity. From this we conclude that the long term fluctuations in the intensity, as observed at the two observatories, describe the same real function and hence their cross-correlation is an even function. Consequently, the origin of the cross-correlation function is defined by the abscissa of its centroid, as marked by the letter C in Fig. 2. This origin is displaced by 50 pulse periods from the zero lag. The r.m.s. error in determining the centroid, σ_T, was estimated by measuring the peak-to-peak value, P, of the undulations in the cross-correlation function outside the main peak shown in Fig. 2. Using $\sigma_T \approx$[width of main peak/10π] [$\tan^{-1}$ $(P/\Gamma_{12}(\mathrm{O}))$], the June 20 and June 22 measurements give $\sigma_T \approx 12$ and 8 respectively. As the observed lag of 50 pulse periods is roughly five times the r.m.s. error in determining the centroid, the lag is most probably real and indicates that a scintillation explanation for the long term fluctuations of CP 1133 is highly likely.

The 6,400 km baseline was at an angle of 60° to the line of sight giving a projected baseline $d=5{,}500$ km. In order to interpret these observations, we will assume that the observed intensity fluctuations are caused by randomly distributed phase changing irregularities giving rise to a stable diffraction pattern of scale size $r_p = a/\varphi_0$, where a is the irregularity size and φ_0 is the r.m.s. value of the phase fluctuations. If the stable diffraction pattern is moving with a velocity v at an angle θ to the projected baseline,

$$r_p = a/\varphi_0 = v\,\tau_0 \qquad (3)$$

where $\Gamma_{11}\ (\tau_0) = 1/\mathrm{e}$. The observed time shift, T, is related to v by the equation

$$v = d|\cos\theta|/T \qquad (4)$$

Because the variations are highly correlated we deduce that

$$r_p > d|\sin\theta| \qquad (5)$$

These three equations specify the following limits for r_p, v, and θ in terms of the observed τ_0, T and d.

$$\begin{gathered} \tau_0 d/T \gtrsim r_p \gtrsim \tau_0 d\ (T^2+\tau_0^2)^{-1/2} \\ d/T \gtrsim v \gtrsim d\ (T^2+\tau_0^2)^{-1/2} \\ \operatorname{arc\,tan}\ (\tau_0/T) \gtrsim |\theta| \gtrsim 0 \end{gathered} \qquad (6)$$

From our observations we therefore deduce that the parameters of the assumed stable diffraction pattern lie in the following approximate ranges:

$$\begin{gathered} 2{\cdot}7\times10^4\ \mathrm{km} \gtrsim r_p \gtrsim 5\times10^3\ \mathrm{km} \\ 92\ \mathrm{km/s^{-1}} \gtrsim v \gtrsim 22\ \mathrm{km/s^{-1}} \\ 80^\circ \gtrsim |\theta| \gtrsim 0^\circ \end{gathered} \qquad (7)$$

The known motions of the pulsar and/or medium with respect to the Earth, differential galactic rotation, solar motion and the Earth's rotation, predict velocities which lie well within the range given by (7). In addition, the limits placed on r_p can be compared with the predictions of interstellar scintillation theory. B. J. R. (unpublished) analysed the frequency and time decorrelation widths in the fading of ten pulsars, to which was fitted a model of strong scintillation in an extended interstellar scattering medium. If the pulsar is at a distance z kpc and is observed at a frequency f MHz, his model predicts

$$r_p = 0{\cdot}75\times10^2 f\, z^{-1/2}\ \mathrm{km} \qquad (8)$$

Taking the distance of CP 1133 to be 0·15 kpc, equation (8) gives $r_p = 8\times10^4$ km, which is of the same order of magnitude as that specified by (7).

The success of the experiment in detecting a time shift between the two sites should open the way for further probing of the diffraction pattern, preferably at three sites simultaneously. This will lead to interesting deductions concerning the motion and size of the interstellar scattering irregularities themselves.

We thank M. H. Cohen and F. D. Drake for useful discussions. The Arecibo Observatory is operated by Cornell University under contract to the US National Science Foundation and with partial support from the Advanced Research Projects Agency.

Long Baseline Interferometer Measurements of CP 0329

THE pulsar CP 0329 has been observed with an interferometer of $4{\cdot}2\times10^6$ λ baseline at a frequency of 408 MHz. The results place an upper limit of 0·02 arc s on the size of the emitting region in position angle 93°. Although the angular size expected from current models[1] and estimates of distance[2,3] is several orders of magnitude smaller than this, the present limit has been established by direct measurement.

The observation was made with the 46 m paraboloid of the Algonquin Radio Observatory and the 26 m paraboloid of the Dominion Radio Astrophysical Observatory using a technique similar to one described previously[4,5]. Signals received in the band 404 to 412 MHz were folded about the local oscillator frequency and recorded in the video band from 0 to 4 MHz. At one station the second local oscillator was adjusted under computer control to give a fringe frequency of 0·1 Hz.

A gating waveform, recorded at one station in time coincidence with the pulsar signal, was used to remove noise from the interpulse interval when the signals were cross-correlated. Fig. 1 shows the result of cross-correlating signals with the optimum delay. The envelope of pulses has a quasi-sinusoidal variation at the expected frequency of 0·1 Hz. Variations in the pulse amplitude combine with receiver noise to cause deviations from a sine wave.

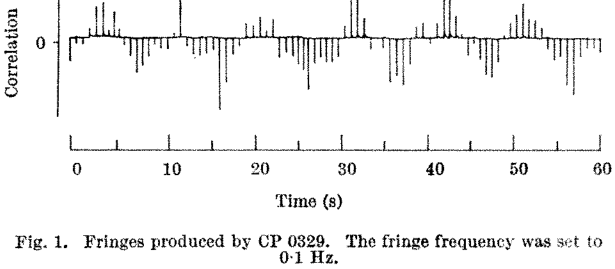

Fig. 1. Fringes produced by CP 0329. The fringe frequency was set to 0·1 Hz.

We thank Dr A. Hewish of the Mullard Radio Observatory for kindly supplying accurate coordinates of the source.

The Extinction Law in the Magellanic Clouds

THE Magellanic clouds contain only small amounts of obscuring matter compared with our galaxy. The maximum reddening observed is of the order of $E_{B-V}=0{\cdot}5$ magnitudes, and *UBV* photometry suggests that the extinction law in the clouds follows the $1/\lambda$ law[1].

The peculiarity of the interstellar extinction law found in the galaxy—a change in slope in the blue region of the spectrum of the linear relation between Δm and $1/\lambda$ (refs. 2 and 3)—provides a useful clue to the composition and size distribution of the interstellar obscuring grains[4,5]. It is therefore of interest to observe the detailed extinction law in the Magellanic clouds particularly in the blue region of the spectrum.

For this purpose, spectra of reddened stars in the large and the small Magellanic clouds were obtained at a dispersion of 86 Å mm^{-1} at H_γ with the 72-inch telescope at Pretoria. Each plate (emulsion IIa0) included spectra of an MC star and a galactic star of the same spectral type. The MC stars were chosen from the list of Feast *et al.*[1] and the galactic stars from those of Gascoigne[6] and Willstrop[7]. The four cloud stars were independently reclassified for this programme by one of us (R. W.), who found agreement within 1/10 of a subclass with the previous classification. In order to avoid spurious effects caused by atmospheric extinction the galactic stars and the time of their observation were chosen so that their zenith distance should be the same as that of their partner MC star. In addition, each plate included a set of spectra of another galactic star taken at different zenith distances to monitor atmospheric extinction. Finally, photometric calibration was imposed on each plate by a multiple slit calibration spectrograph.

Stellar and calibration spectra were recorded using a digitized Joyce-Loebl microdensitometer, from which fifteen calibration curves were drawn by computer in the range 4000 Å to 5000 Å and applied to the stellar spectra which were recorded at fifty points within the same wavelength range. A number of spectra of four Magellanic cloud stars and three galactic comparison stars yielded four sets which are listed in Table 1.

The magnitude differences were normalized so that the colour excess between $1/\lambda=2{\cdot}0$ μm^{-1} and $1/\lambda=2{\cdot}25$ μm^{-1} is one magnitude and the extinction is zero at $2{\cdot}0$ μm^{-1}.

Table 1. SUMMARY OF THE DATA

Reddened star (Magellanic)			Comparison star		
HD	Sp	*B–V*	HD	Sp	*B–V*
4976	B6I	0·14	6882	B6V	–0·10 (galactic)
5291	B6Ia	0·05	6882	B6V	–0·10 ,,
270754	B1. 5Ia	0·10	160578	B2IV	–0·23 ,,
270086	A1 Ia–0:	0·24	221006	Aop	–0·18 ,,
4976	B6I	0·14	5291	B6Ia	0·05 (Magellanic)
270086	A1 Ia–0:	0·24	268675	A0Ia	0·05 ,,

Because the Magellanic cloud stars were all supergiants, which could not be matched readily by similarly luminous unreddened stars in the galaxy, main sequence stars had to be used for comparison and a correction for luminosity class applied to the magnitude differences. The correction, based on Ardeberg's data[8], ranged for our case from 0 to 0·12 m in the interval 2·25 μm^{-1} to 2·5 μm^{-1}, and had the effect of increasing the difference at the shortwave end. The corrected magnitude differences are shown by filled circles in Fig. 1. The combined errors due to uncertainty in spectral class and photometry at various wavelengths are also shown; the relatively large errors are due to the normalizing factors required because of the small reddening. It should be pointed out that the observed extinction may include a contribution from the galactic foreground which, however, is small ($E_{B-V}\sim 0{\cdot}05$ m) (refs. 9 and 10) compared with the average reddening in the MC stars we have used ($E_{B-V}\sim 0{\cdot}3$ m).

Our data also include two pairs of Magellanic cloud stars of the same spectral type and luminosity class but of different reddening. By differencing these pairs, shown as open circles in Fig. 1, the difficulties of luminosity class discrepancy and foreground reddening are avoided; on account of the smaller difference in reddening, however, the errors are larger than for the other pairs.

The observations are compared in Fig. 1 with the galactic extinction laws in the directions of Cygnus[11] and Perseus[12]. These preliminary observations suggest that the extinction law in the Magellanic clouds resembles the Perseus rather than the Cygnus law and that the change in slope in the neighbourhood of $1/\lambda=2{\cdot}3$ μm^{-1} is similar to that found in the galactic extinction laws. This result, if confirmed by later observations, is important. The interstellar features of our galaxy are represented in the visible wavelength region by two extinction laws—the Cygnus reddening law representing the majority of stars in the Cygnus and Cassiopeia regions, and the Perseus law representing the stars in the direction of the galactic anticentre[13]. Other evidence of a major discontinuity in stellar and interstellar features in the galaxy in the direction of Perseus points to the possibility that the composition and size distribution of grains in this region are distinctly different from those in the Cygnus region[13,14].

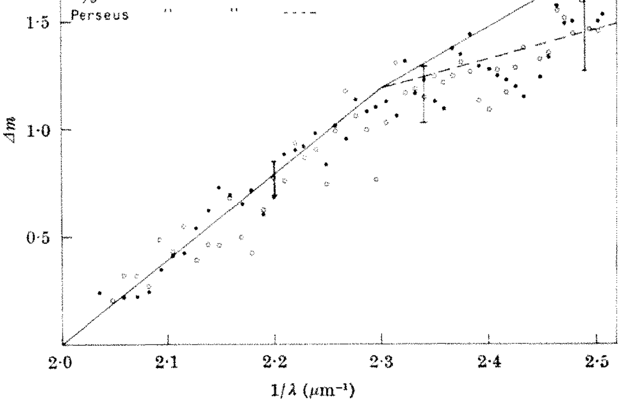

Fig. 1. The extinction law in the Magellanic clouds is compared with the galactic extinction laws for the direction of Cygnus and Perseus.

The present result indicates that the composition, size and optical properties of dust grains in the Magellanic clouds resemble those in the anticentre region of the galaxy.

Observation of Structure in Čerenkov Pulses from Extensive Air Showers using Fast Techniques

Light pulses from the night sky were first observed in 1952 by Galbraith and Jelley[1] following Blackett's suggestion[2], and then by other authors (see ref. 3 for a review). These light flashes are due to the Čerenkov radiation produced essentially by the electronic component of extensive air showers (EAS) traversing the atmosphere.

In an experiment on the temporal structure of the Čerenkov flashes carried out at the Testa Grigia Laboratory (altitude 3,500 m above sea level) we detected three anomalous Čerenkov pulses. In two cases (A and B) the pulse was double, and there were two light pulses with a short relative delay (3 and 4 ns). The rise-time of the second pulse was slower than usual. Event A is reproduced in Fig. 1. In one case (C) we observed a light pulse slower and longer than usual.

We used two very high-speed RCA photomultipliers C 70045 D with their cathodes at the focal points of two parabolic mirrors with parallel optical axes, diameter 60 cm, focal length 29 cm and angular acceptance ±3° from the zenith. We then recorded the correlation between the two RCA systems and a coincidence from three 56 AVP Philips photomultipliers at the foci of three spherical mirrors of diameter 50 cm, angular acceptance ±2° and positioned on the vertices of a triangle of area 30 m². The outputs from the two fast RCA photomultipliers were fed to two Tektronix 519 oscilloscopes, and the pulses were recorded photographically. The vertical sensitivity was 10 V cm^{-1} and the sweep speeds 5 ns cm^{-1}. The response of the detecting apparatus to a light pulse of 0·1 ns had a rise-time of 0·5 ns.

The photocathode was screened with an ultraviolet filter (a 50 per cent aqueous solution of $CoSO_4.7H_2O$ in a quartz container). This arrangement improves the signal to background ratio. The threshold sensitivity of our apparatus was estimated using Čerenkov pulses of known intensity produced by cosmic ray muons in distilled water and lucite layers 3 and 15 cm thick. This gives an EAS threshold energy for detection $\simeq 10^{12}$ eV.

We observed 455 EAS Čerenkov flashes by coincidences of the five photomultipliers in a run of 70 h on moonless clear nights. Table 1 lists the characteristics of the three anomalous pulses as observed by the two RCA photomultipliers, together with those of normal pulses. In particular we notice that: (*a*) the first pulse of events A and B is larger in amplitude than the second; (*b*) the duration at half maximum of the first pulse (σ_1) of events A and B is in good agreement with the mean value $<\sigma>$ for normal pulses, while in event A $\sigma_2 > \sigma_1$; (*c*) in event C $\sigma_c \gg <\sigma>$.

Table 1. THE THREE ANOMALOUS PULSES

	E		W		E		W		E	W
	h_1	h_2	h_1	h_2	σ_1	σ_2	σ_1	σ_2	delay	(ns)
Mean value from 455 EAS	2·5		3		1·8		1·7			
Event A	2	1·5	2	1·8	1·5	7	2	6	4	4
Event B	2	1·5	2	1·5	2	2	2	2	3	3
Event C	1·5		2		8		9			

h_i = pulse height (V); σ_i = Half-maximum duration (ns).

E, W refer respectively to the two independent RCA photomultipliers in coincidence; subscripts 1, 2 refer respectively to the first and second pulse.

These anomalous pulses may have a physical or an instrumental explanation. We considered two instrumental causes: (1) the probability of having two spurious after pulses within 4 ns on two independent RCA tubes turned out to be $\sim 10^{-5}$; (2) the probability of casual coincidences due to light pulses produced by scintillation or Čerenkov effects in the photocathode glass or in the filter by EAS particles is $< 10^{-6}$. In any case, the photomultipliers look downward and only detect Čerenkov radiation after reflexion.

One can also exclude the following physical effects: (1) casual coincidences from independent EAS of 10^{12} eV, the probability being $< 10^{-6}$; (2) the second pulse arising from a successive interaction of the primary proton with an energy above the threshold—the delay should be negligible compared with that measured; (3) the second pulse is unlikely to be due to a local effect in an ordinary EAS, such as a single particle lagging behind the shower front and producing Čerenkov light in air inside the cone viewed by the mirrors. The probability of this event is small and the second pulse should be very short, in disagreement with our observation.

A possible interpretation (apart from extreme fluctuations in a normal shower) may be derived from the successive interactions of a primary nucleus in the atmosphere. A simple Monte Carlo calculation shows the possibility of obtaining the observed delays if the energy of the nucleus is $\sim 10^{12}$ eV. The presence of a very massive particle,

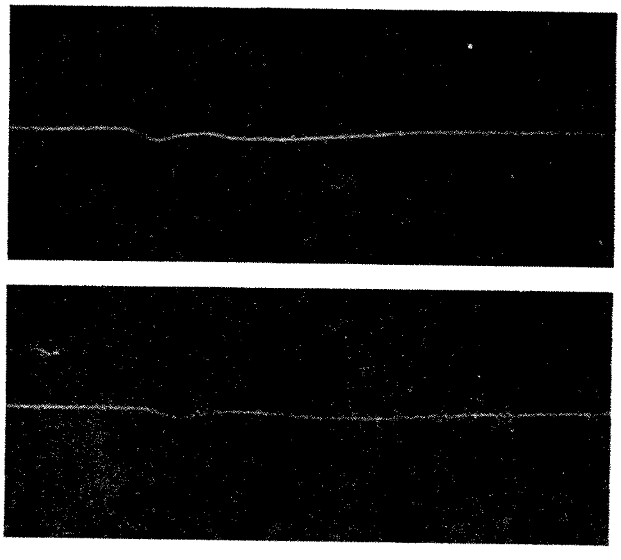

Fig. 1. Double Čerenkov pulse from an EAS (event A, Table 1) as observed by two independent fast channels. The heights of the first pulses are 2 V and of the second 1·8 V and 1·5 V respectively; relative delay 4 × 10⁻⁹ s.

generated in the first N–N collision, also could possibly explain the effect. A simple model shows that such a particle could produce a detectable shower with the measured delay observed in events A and B if the particle mass is ~ 10 GeV c^{-2} and its energy $E_0 \sim 10^{12}$ eV. Further work is under way at the same altitude (3,500 m).

It seems to us that the structure in the Čerenkov pulses which we have obtained with the fast technique opens a new approach to the study of air showers.

Topside Ionosphere of Venus and its Interaction with the Solar Wind

The abrupt termination of the daytime ionosphere of Venus at about 500 km observed with the Mariner V two-frequency occultation experiment provides an extremely interesting picture of the direct interaction of the solar wind with a planetary ionosphere[1,2]. It has been suggested that a pseudo-magnetopause is formed by magnetic fields carried along by the solar wind and forced to pile up on the topside of the highly conducting planetary ionosphere[3,4]. This magnetic obstacle then interacts with the super-alfvénic and supersonic solar wind to form a bow shock; evidence for such a bow shock has been obtained by experiments on Mariner V and Venera IV (refs. 2 and 5).

We have used the observed properties of the solar wind[2] to determine order of magnitude estimates of the characteristic parameters in this interaction.

A pressure balance at the stagnation point formed with the streaming pressure of the solar wind leads to a magnetic field build-up of approximately 50 γ. A balance between the streaming pressure of the solar wind $P_w = K\,n\,mv^2 \cos^2 \Psi$ and the plasma pressure $P_c = Nk(T_e + T_i)$ in the topside ionosphere of Venus is consistent with the sharp cut-off in the electron density profile. At $\Psi = 45°$ from the sub-solar point where the electron density of the topside ionosphere was observed to be $N \simeq 10^4$ cm^{-3} at the 500 km cut-off ("ionopause")[1], we calculate the streaming pressure of the solar wind to be about $8 \cdot 8 \times 10^{-9}$ dynes cm^{-2} using an accommodation coefficient $K = 1$ as is frequently done for the Earth's magnetosphere[6]. With this solar wind pressure and the observed electron density of the topside ionosphere, we obtain about 6,000 K for the plasma temperature $(T_e + T_i)$ of the topside ionosphere. In the following we shall discuss the important constraints which the solar wind interaction places on a self-consistent model of ionospheric temperatures and densities.

The presence or absence of a magnetic field within the ionosphere has important consequences for the structure of the Venus ionosphere. There are two extreme cases: (1) where the presence of an essentially horizontal magnetic field inhibits thermal conduction across field lines, and (2) where either because of the complete absence of a magnetic field or the presence of a tilted magnetic field the thermal structure is controlled by parallel heat conduction. An induced magnetic field due to the interaction of the solar wind with the conducting ionosphere or the presence of a small intrinsic planetary magnetic field can lead to a non-horizontal field within the Venus ionosphere. The upper limit for such a magnetic field inside the ionosphere is estimated to be about 40 γ (J. L. Blank and W. R. Sill at the IAGA Symposium, Madrid, 1969). The following discussion assumes the more likely case of a non-horizontal magnetic field within the Venus ionosphere using a thermal conduction coefficient of $0 \cdot 25\, K_{\|}$. It is not our intention to discuss the detailed ionic composition, so we selected a relatively simple photochemical model for the lower regions of the ionosphere based on the work of McElroy[7]. We have taken CO_2 to be the dominant heavy neutral species at 100 km, and H and He are taken to be the important light neutral constituents. We also have investigated the effect of the presence of H_2 or deuterium (D), but their presence does not affect our results significantly. As a result of using hydrostatic equilibrium for the distribution of the neutral gas density, H and He become the dominant species at higher altitudes. It therefore follows that the ionization peak at about 130 km will be controlled by the neutral CO_2, while the charged particle pressure in the topside is strongly influenced by H and He. For the light ions H^+ and He^+ we have solved the usual balance equations of hydrostatic pressure including gravitational and electrical forces. Combining these with the equations arising from the thermal balance in a multicomponent plasma (including the neutral gases) a self-consistent solution for the temperatures and densities has been obtained[8].

We have selected several boundary conditions based, wherever possible, on published values. At the lower boundary of 100 km we used a neutral temperature of $T_n = 250°$ and a CO_2 density of 2×10^{13} cm^{-3} comprising at least 99 per cent of the total density. The remaining 1 per cent or less was adjusted so that the corresponding topside plasma pressure balances that of the solar wind and simultaneously approximates the observed scale height of electron density. Because the light ion composition is experimentally unknown, we have assumed H^+ (or D^+) and He^+ to be the main constituents of the topside ionosphere. The electron density $N = [He^+] + [H^+] + [CO_2^+]$ was selected to match the observed electron density at 500 km.

Fig. 1 shows the computed ionospheric model with He^+ as the dominant ion. The electron temperature has the value of $T_e = 4{,}090$ K, as compared with the ion temperatures which have a value of $T_i \simeq 1{,}900$ K, considerably higher than the neutral gas temperature $T_n = 550$ K. The

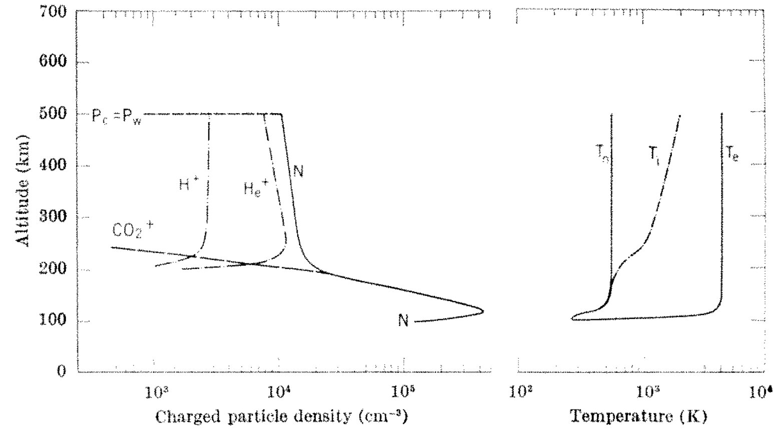

Fig. 1. Charged particle densities and temperatures for the Venus ionosphere when the electron thermal conductivity is $0 \cdot 25\, K_{\|}$. The dashed line $P_c = P_w$ represents the cut-off in electron density ("ionopause") arising from the pressure balance between the solar wind and the charged particles of the Venus ionosphere. The actual ionopause is expected to be a layer whose thickness should be of the order of a proton gyroradius, instead of the abrupt cut-off shown.

peak of electron density and the scale height of topside electron density for this model are in good agreement with the Mariner occultation data.

A similar ionospheric model satisfying the observed conditions is one where H^+ (or D^+) is the dominant ion in the topside ionosphere. Although such a model also gives reasonable agreement with the observed values, we argue that the high value required for the H^+ density (and/or D^+ density) in the topside ionosphere seems unlikely, because the observed density of neutral hydrogen is thought to be relatively low[9] and, in contrast to the Earth, H^+ is produced by photoionization rather than by charge exchange. We therefore favour the model in which He^+ is the dominant topside ion with relatively hot electrons compared with the ion and neutral gases.

In the other limiting case of a horizontal rather than a slightly inclined magnetic field, the thermal structure of the topside ionosphere is significantly different because heat conduction does not play a significant part due to the inhibiting effects of this horizontal magnetic field. In this case, the electron temperature is higher and the ion temperature is lower than in the model presented in Fig. 1.

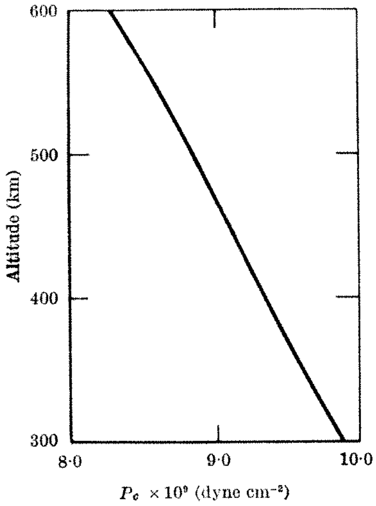

Fig. 2. Charged particle pressure $P_c = Nk(T_e + T_i)$ in the topside Venus ionosphere. At the altitude of the ionopause (500 km), $P_c = 8.8 \times 10^{-9}$ dyne cm^{-2}.

Fig. 2 shows the total pressure distribution based on the density and temperature distributions of Fig. 1. The pressure curve extended to 600 km was obtained by solving the density and temperature equations simultaneously with pressure balance between solar wind and ionospheric plasma pressure at 500 km. The very slow pressure decrease with altitude suggests that the altitude at which the ionosphere terminates (ionopause or anemopause[2]) is a strong function of solar wind pressure. If the solar wind pressure changes by a small amount, our model predicts a substantially unchanged ionosphere with an ionopause at a different altitude. It also suggests that the ionospheric boundary is flat-nosed at the sub-solar wind point and somewhat bulged out near the terminator due to the effect of the aspect angle in the pressure balance equation. Because the streaming pressure of the solar wind on the night side of Venus is negligible, the ionosphere would there extend to considerable altitudes as reported by Mariner V (ref. 1).

Hoyle–Narlikar Quantization of Wheeler–Feynman Electrodynamics

Hoyle and Narlikar[1] (HN) have proposed a quantized version of the Wheeler–Feynman[2,3] (WF) theory of classical electrodynamics. It is the purpose of this report to point out that the HN treatment of spontaneous emission deviates from the WF prescription. This is true even in the classical limit; however, in this limit the numerical effects of two different deviations cancel.

The WF theory is based on the postulates that charged particles interact via time symmetric ($\frac{1}{2}$ retarded + $\frac{1}{2}$ advanced) electromagnetic fields, and that there is no self interaction. The theory then takes into account the response of all charged particles in the universe to the field of each accelerated charge. The response field accounts for radiation reaction; it also re-establishes the full retarded field around each accelerated particle and defines a universal direction of time in which all the retarded potentials point.

The WF prescription for computing the response of the universe[2] to the field of an accelerated particle a is to let each charged particle b in the universe be excited by the full retarded and attenuated field of a, then let b react on a with one half its advanced field, unattenuated. (The full retarded and attenuated field is used for the action of a on b in order to allow for fields of particles other than a on b. No such allowance is necessary in the case of the action of b on a, because a summation on the contributions of all charged particles b in the universe is carried out explicitly.) The reaction field in the HN treatment is the full advanced field, attenuated.

HN quantize by Feynman's method of summation over all classical trajectories. The interaction term in their Lagrangian is $\int A^{(a)}_{\mathrm{ret}}(b(t))\cdot\dot{b}(t)\mathrm{d}t$. This may be transformed

$$\mathrm{e}\int A^{(a)}_{\mathrm{ret}}(b(t))\cdot\dot{b}(t)\mathrm{d}t = 2\mathrm{e}^2\iint\delta((a(t')-b(t))^2)\dot{a}(t')\cdot\dot{b}(t)\mathrm{d}t'\mathrm{d}t = \mathrm{e}\int A^{(b)}_{\mathrm{adv}}(a(t'))\cdot\dot{a}(t')\mathrm{d}t' \qquad (1)$$

The reaction of b on a is therefore automatically the full advanced field. (We adopt the notation where a stands for the four-vector position of particle a. The middle expression in equation (1) describes retarded or advanced interaction according to the relative position of a and b. HN choose a segment of the world line of particle a and in the vicinity of its future light cone a segment of the world line of particle b. This choice makes the action of a on b retarded and the action of b on a advanced.) Because attenuation is introduced into the interaction before the summation on classical trajectories is completed, however, the reaction of b on a is also attenuated.

In the classical limit, the summation over all classical trajectories may be replaced by the use of the trajectory corresponding to stationary action. When this is done, we find particle *b* moving in the retarded and attenuated field of particle *a*, and particle *a* moving in the full advanced and attenuated field of particle *b*. The use of the full advanced field rather than half the advanced tends to double the radiation reaction. The attenuation tends to cut it down—as it turns out—exactly in half.

The reason for the last point is that the response field from a layer of optical thickness $d\tau$ turns out to be proportional to $e^{-\tau}d\tau$ (ref. 2). The factor $e^{-\tau}$ is due to the attenuation of the field of *a* at *b*. When the reaction is also attenuated, an extra factor $e^{-\tau}$ is required, and the contribution becomes proportional to $e^{-2\tau}d\tau$. In the final result for the response field, the inclusion of attenuation has the effect of replacing $\int_0^\infty e^{-\tau}d\tau = 1$ by $\int_0^\infty e^{-2\tau}d\tau = \frac{1}{2}$.

Whether the effects of doubling the response field and of attenuating it cancel also outside the classical limit should be made clear.

Microbarograph Observation of Acoustic Gravity Waves

MAY I comment on the recent letter in *Nature* by Murty and Curry[1] on microbarographic observation of acoustic gravity waves.

Events such as these authors describe are rather commonplace in Victoria, Australia, and one such occurrence has been recorded[2] at some length, while Pothecary[3] has noted an English case. Although it would be rash to claim that the processes responsible for exciting gravity waves in the atmosphere are fully understood, it is recognized here that pronounced and sustained pressure oscillations, of amplitude of the order of a millibar, are almost invariably associated with a shallow layer (1–2 km) of cold air, underlying much warmer air. This commonly occurs when a shallow but intense cold front moves north or north-eastward over Melbourne and becomes almost stationary. In most cases it is also possible to find evidence of precipitation, which may be associated with thunder, originating in the warmer air and penetrating the inversion, somewhere within, say, a hundred miles. The conclusion has been drawn that excitation by precipitation, or its concomitant downdraughts, of gravity waves on a marked low level inversion is responsible for the observed oscillations of surface pressure. Ramm and Warren[4] have given a quantitative treatment of the processes involved.

It is suggested that your correspondents should pay some attention to the vertical and horizontal density and wind distribution at the time of the phenomenon they describe.

Concentration Wave Propagation in Two-dimensional Liquid-phase Self-oscillating System

OSCILLATING chemical reactions are interesting, not only in themselves but as models of a number of important biological processes[1–5]. Oscillating reactions have been described in which cerium (or manganese) ions catalyse the oxidation of analogues of malonic acid by bromate[6–8]. Oscillations in the concentrations of oxidized and reduced forms of the catalyst cause oscillations in the solution colour, while stirring leads to forced synchronization of oscillations throughout the whole volume. In the absence of stirring, periodic propagation of concentration waves occurs in certain conditions, and such a phenomenon in a one-dimensional system (a long tube) has been described[9,10]. Our work deals with patterns in a thin layer of solution (two-dimensional system).

Fe (1,10-phenanthroline)$_3$ is a convenient indicator for observation of spatial effects in our system. Ferroin and Fe (2,2′-dipyridyl)$_3$ could also be used, not only as indicators but also as catalysts, and it seems that a number of variable valence ions with one-electron transition and standard potential between 0·9 and 1·6 V may be used as catalysts in the system. In the present work, the system bromate, bromomalonic acid (BMA), ferroin was used. BMA was prepared by bromination of malonic acid by bromate–bromide mixture in acidic aqueous solution.

$$3\ CH_2(COOH)_2 + 2\ HBr + HBrO_3 = 3\ CHBr(COOH)_2 + 3\ H_2O$$

Similar results are obtained with BMA prepared by the method described by Conrade[11]. The reaction was performed at room temperature (about 20° C) in Petri dishes about 100 mm in diameter, with a solution layer about 2 mm deep.

Fig. 1 shows a series of sixteen photographs taken at one-minute intervals. In the first photograph, the catalyst is completely reduced, and subsequent photographs show it starting to be oxidized at particular points (leading centres), from which circular waves of oxidation are propagated. The fourth photograph shows oxidation taking place in areas not reached by these waves. The time when these transitions take place is determined by the oscillation period (T_0) of the main part of the space, which is equal to the system oscillation period in the case of forced synchronization by stirring. The next photographs show waves coming from leading centres (with $T < T_0$) oxidizing all the space step by step. When the waves coming from different leading centres collide, mutual annihilation takes place, with the point of collision, situated on a straight line between two leading centres, gradually moving towards the leading centre with the longer period. When a wave from a high-frequency leading centre reaches a low-frequency centre, the latter disappears, and, in the ideal case, a single leading centre with the highest frequency eventually synchronizes the whole space. In most experiments, however, some fronts break at the end of the process and space disorganization takes place (photographs 12–16).

Qualitatively distinctive patterns, for example, radial symmetric and small-cell patterns, are observed at other initial reactant concentrations. Those shown in Fig. 1 resemble Liesegang rings (LR), but it should be emphasized that the phenomenon described differs from LR in two significant features. First, in this case, there are progressive concentration waves while the sediment rings in the LR phenomenon are motionless. Second, LR-pattern is a fixed imprint of a reaction which has proceeded, but in our case the space structure is supported at the expense of redox reaction energy.

We consider here the simplest model of wave propagation in the system. In a one-dimensional system (a thin tube with length L, filled by solution), see Fig. 2, let all

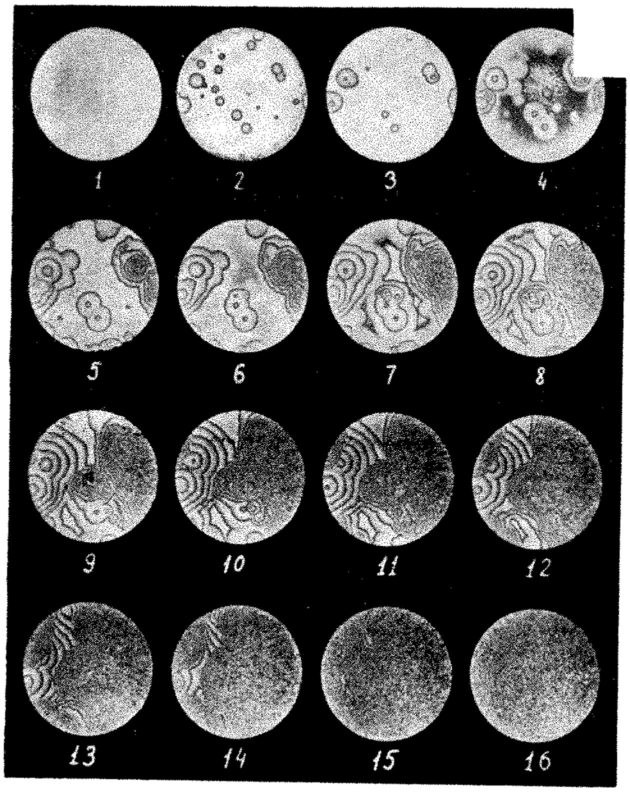

Fig. 1. Concentration wave propagation in two-dimensional self-oscillatory chemical system. Ring diameter equals 100 mm. Initial reactant concentrations (in mol/l.): [BMA] = 0·125; [$NaBrO_3$] = 0·3; [$Fe(phen)_3$] = 0·003; [H_2SO_4] = 0·37.

the points in the system (except X_A and X_B) possess a period of self-oscillation equal to T_o. Leading centres (A and B) have periods equal to T_A and T_B

$$T_A < T_B < T_O$$

The following features of the system, obtained experimentally, form the basis of the model. Relaxation oscillations take place at every point in the space. The period of oscillation is distinctly divided into two phases: an oxidation phase and a reduction phase. The catalyst exists in oxidized form during a small part of the oscillation period. In Fig. 2 the oxidized state is represented by black lines (in the same manner as in Fig. 1) and the line width corresponds to the duration of the oxidation phase. The velocity of wave propagation (V_o) is constant throughout the space and oscillation periods (T_A, T_B and T_o) are constant. When two waves collide, they cancel each other out.

In this model, waves spread in the following manner. All the space is initially in the reduced state, and at $t = 0$ all the points pass into the oxidized state and then the system returns to the reduced state. At $t = T_A$ transition into the oxidized state occurs at the point X_A from which a wave begins to spread with velocity equal to V_o. At $t = T_B$ the same process occurs at X_B. At $T = T_O$, transition into the oxidized state occurs in all parts of space free from waves coming from leading centres, and this annihilates one (external) wave from every leading centre. In the absence of this general oxidation, the velocity of propagation of the zone synchronized by one particular leading centre equals V_o. With general oxidation, the mean velocity of propagation of the zone by leading centres is given by

$$V_i = V_o\left(1 - \frac{T_i}{T_o}\right) \text{ ; with period } T_i$$

At

$$t = \frac{T_o}{V_o} \cdot \frac{X_B - X_A}{2T_o - T_A - T_B}$$

waves from centres A and B collide, and the point of collision then moves towards X_B with mean velocity

$$V = V_o \frac{T_B - T_A}{T_B + T_A}$$

The complete development of the picture in time is accompanied by the appearance of some characteristic points in X,t-space (Fig. 2). At point G, time t_G, general oxidation ceases to the left, from centre A.

$$X_G = 0; \; t_G = T_O \frac{X_A}{V_o(T_o - T_A)}$$

At C, general oxidation ceases between A and B.

$$X_C = \frac{X_B(T_o - T_A) + X_A(T_o - T_B)}{2T_o - T_B - T_A}; \; t_C = \frac{T_o(X_B - X_A)}{V_o(2T_o - T_B - T_A)}$$

At D, the centre B is captured by higher-frequency centre A.

$$X_D = X_B \; ; \; t_D = \frac{T_B(X_B - X_A)}{V_o(T_B - T_A)}$$

It should be noted that the time at which this takes place (t_D) does not depend on general oxidation being present in the system. At E, despite the disappearance of the centre B, its waves continue to propagate in the triangle DEH, and waves from centre A begin to interact with the general oxidation patterns.

$$X_E = \frac{X_B(T_O - T_A) - X_A(T_O - T_B)}{T_B - T_A} \; ; \; t_E = \frac{T_O(X_B - X_A)}{V_O(T_B - T_A)}$$

At F, waves from the higher-frequency centre A fill the whole tube.

$$X_F = L; \; t_F = \frac{T_O(L - X_A)}{V_O(T_O - T_A)}$$

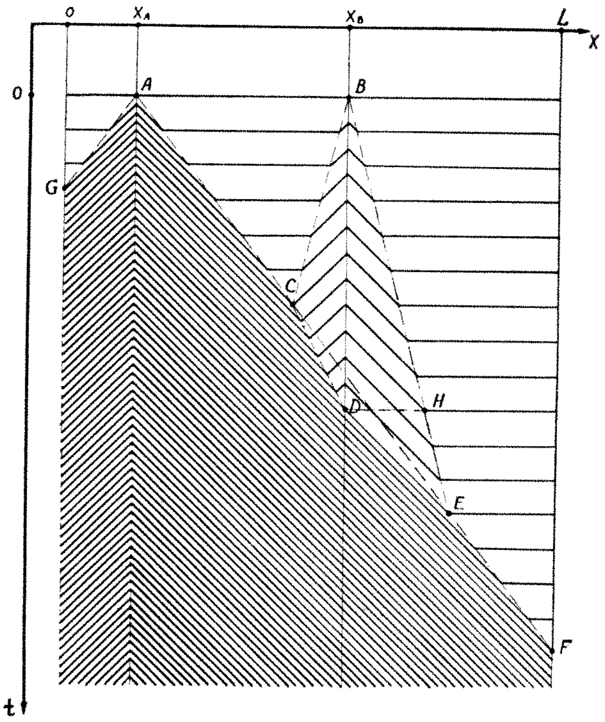

Fig. 2. Wave propagation in one-dimensional model.

It should be noted that t_F does not depend on the existence of the centre B.

All these events may be observed in a two-dimensional model on the straight line passing through two leading centres.

Similar models have been applied to the explanation of impulse propagation in cardiac muscle[12-14].

We thank Dr V. I. Krinsky for useful discussion.

Solid State Chemistry and Colloid Chemistry

THE properties of the solid state are often ignored in studies of lyophobic colloidal phenomena. Colloid chemists concentrate on the liquid phase when trying to interpret experiments, and consider the solid phase as relevant only in the role of an adsorbent or of a charged surface.

In 1947, Grimley and Mott[1] pointed out how solid state properties, in particular the type and the number of lattice defects, might influence colloidal phenomena. Until recently, very little attention was paid to their article, except by Mackor[2] and by Ottewill and Woodbridge[3], who rekindled the interest in Grimley and Mott's article. Recent experiments carried out in our laboratory have shown that the introduction of divalent anions or cations to AgBr crystals causes a considerable shift of the point of zero charge (p.z.c.) of AgBr[4]. The p.z.c. of AgBr is defined as that concentration of silver ions in solution (Ag_s^+) for which the crystals carry no net charge. According to Grimley and Mott the net charge in the crystals depends on the equilibrium $Ag_s^+ \rightleftarrows Ag_i^+$, or the p.z.c. depends on the concentration of interstitial silver ions (Ag_i^+) in the crystals. The introduction of S^{2-} in the crystals increases $[Ag_i^+]$ and hence the p.z.c. is expected to shift to a higher $[Ag_s^+]$ (lower $pAg^{p.z.c.}$). Conversely, the introduction of Pb^{2+} in the crystals decreases $[Ag_i]$, and the p.z.c. is expected to shift to a lower $[Ag_s]$, in agreement with the experimental data presented in Table 1.

A second property of the solid phase, which has to be considered, is the potential difference which exists between the surface and the bulk of the crystal due to a surface charge in the crystal, as pointed out by Lehovec[5], Kliewer[6] and Trautweiler[7]. We note that the origin of this surface charge is not the same as the surface charge usually assumed in colloid chemistry. The "colloid chemical" version of the boundary charge is an adsorption or desorption of ionic species on the surface from the solution. The "solid state chemical" version of the boundary charge is a different concentration of interstitials and vacancies in the surface region compared with the bulk of the crystals.

Table 1. POINTS OF ZERO CHARGE AT 25° C OF SULPHUR AND LEAD-DOPED AgBr

Dope	—	S	S	Pb	Pb	Pb	Pb
Dope, mole fraction (units 10^{-4})	—	0·44	4·7	1·35	1·45	1·45	5·0
$pAg^{p.z.c.}$	5·40	3·47	2·63	9·61	9·56	9·62	10·37

The existence of this surface charge leads to a modification of Grimley's theory[4,8,9]. From measurements of the p.z.c. of AgBr it is then possible to calculate the concentrations of lattice defects and the surface charge of AgBr. It turned out that the fraction of the lattice defects at 25° C in pure AgBr is $10^{-7\cdot2}$ and the surface charge is $-0\cdot011$ μCi/cm². From measurements of the latent image Trautweiler found $10^{-7\cdot6}$ and $-0\cdot03$ μCi/cm² respectively, while the extrapolated value from conductivity measurements is $10^{-7\cdot5}$ for the fraction of lattice defects. There is fair agreement between these data. In our case it has thus been possible to deduce data of the "dry state" from "wet" experiments.

Generally speaking, the interaction between the disciplines of colloid chemistry and of solid state chemistry is two-fold. First, the properties of the solid phase do influence the colloidal properties when such a solid is dispersed in a liquid, and second the magnitude of certain parameters of the solid phase can be deduced from colloidal measurements. In the previous section this point of view was demonstrated: the p.z.c. of AgBr is determined by the concentrations of lattice defects in AgBr, and these concentrations can be calculated from the measured p.z.c. of AgBr.

A second example is the relationship between the net charge of AgI and the silver ion concentration in solution. Instead of the usual assumption of a Stern layer in the liquid phase, with a dielectric constant of about 5 and a capacity which is a function of charge, the experimental data could be explained fairly well by a theory based on lattice defects and a fixed surface charge in AgI[9]. The fraction of lattice defects of AgI at 20° C is $10^{-2\cdot8}$ and the surface charge is $-1\cdot2$ μCi/cm²—deduced from fitting the experimental data to the theory.

As a third example, consider measurements of the time necessary for equilibration in a colloidal system. If diffusion in the solid is the rate determining process, it should be possible to calculate the diffusion coefficient D of the most mobile type of lattice defects from the time for equilibration, which is roughly equal to $V\varepsilon RT/16\pi F^2D$, where V is the molar volume, ε the dielectric constant of the solid, and R, T and F have their usual significance[4].

As a fourth example, a better understanding of the magnitude of the zeta potential might be obtained by noting that only part of the total potential jump between the bulk solid phase and the bulk liquid phase is situated in the liquid[3,9].

Not only colloidal phenomena but also electrochemical phenomena are influenced by lattice defects, as pointed out by Awad[11], who measured the overpotential at silver anodes covered with anodically deposited AgBr layers, and by Hall and Bruner[12], who measured the electrical resistance of thin AgBr membranes between two $AgNO_3$ solutions.

Whether a secondary electrode of the type metal/insoluble metal salt behaves as a reproducible and accurate electrode probably also depends on the solid state properties of the salt. In particular the concentrations and the diffusion coefficients of the lattice defects must have a certain minimum value in order for equilibrium to be quickly established. Silver halides, for example, which make very good secondary electrodes, have a large concentration of lattice defects with high diffusion coefficients. It may be that other secondary electrodes can be improved by doping, thus increasing the number of lattice defects.

Macro-lattice from Segregated Amorphous Phases of a Three Block Copolymer

THERMOPLASTIC elastomers represent a new and important family of polymeric materials. One of the most representative examples contains three blocks, styrene/butadiene/styrene (SBS), within a chain. At ambient temperatures the two chemical species separate. The *B* phase is rubbery, and provides the matrix for the highly dispersed *S* phase which is glassy. Owing to the molecular connexion between the two, the *S* phase acts like a cross-link and thus creates a network. At high enough temperatures this cross-linking effect due to the *S* phase is removed and the object becomes mouldable.

The dispersed *S* phase has been observed to consist of spherical or rod-like particles or to exist in the form of layers[1-5]. A high degree of ordering is indicated from electron micrographs of solvent cast films, in which a hexagonal array of circles can sometimes be seen[1,3,5]. Low angle diffraction patterns have been reported to show a discrete diffraction ring corresponding to a spacing of the same order as observed electron microscopically[2]. We report here a further low angle X-ray effect indicative of a quite unexpected degree of regularity in the arrangement of the dispersed particles, which we believe represents an unusual kind of ordering in solid substances. We report only the effect itself in its most pronounced form, leaving the particulars to be described elsewhere[6].

The material was an *SBS* polymer with 25 per cent *S* content as manufactured by Shell Co. under the trade name Kraton 102. The molecular weight of the *S* block is 10^4 and that of the *B* block $5\cdot5\times10^4$ (ref. 7). We obtained the polymer in the form of an extruded rod of 9 mm diameter. Discrete spot-like X-ray diffraction effects were observed at low angles, the pattern displaying hexagonal symmetry about the plug, that is, extrusion direction. The ordered appearance of the pattern was apparent from the outset but could be further enhanced by heat treatments. Fig. 1 shows an example with the beam along the extrusion direction. Here the hexagonal spacing corresponds to 260 Å. With the beam perpendicular to the extrusion direction the pattern consisted of a set of sharp reflexions along the zero layer line but nowhere else. It is clear that we have an ordered arrangement of the dispersed phase comparable with that of atoms in a crystal lattice except that the scale of the periodicity is in the range of 300 Å. The individual "crystal" thus defined can assume macroscopic dimensions and in the most regular case observed so far can make up the whole cross-section of the plug.

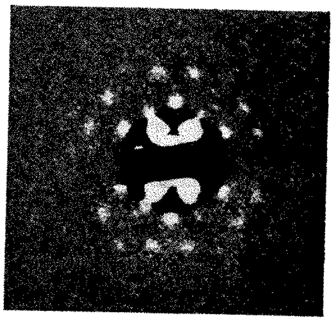

Fig. 1. Low angle X-ray diffraction pattern from an extruded Kraton cylinder with the beam parallel to the cylinder axis. Two of the six strongest reflexions obscured by backstop. Centre of pattern printed darker.

The patterns obtained along the two directions are consistent with a hexagonal packing of cylinders which are many times as long as wide and could well be of "infinite" length. The cylinder diameter could be assessed in two independent ways: (*a*) from the measured hexagonal spacing and from the known composition and macroscopic densities of the polymers; (*b*) from the missing second order of the strong hexagonal spacing in Fig. 1 interpreted as arising from the first zero of the first order Bessel function (the Fourier transform of a cylinder). Both assessments give a value of 150 Å within an uncertainty of about 10 per cent. This is half the centre-to-centre distance between the nearest neighbour cylinders.

Various experiments were performed by melting and stretching the material both uniaxially and biaxially. Such treatments altered and reformed the patterns in characteristic ways, the hexagonal axis always being along the stretch direction (or directions), which is consistent with the stress aligning the cylinders. Clearly this opens up a new field of texture studies in terms of the macro-lattice. This would differ from deformation studies in conventional crystals in as far as both the lattice and the dispersed units themselves could be affected by stress. The effect of the *SB* block ratio and that of the total chain length would also be expected to influence the "crystal", so examination of samples with different chemical composition should be of further interest.

It has been pointed out previously[2,3] that the size, shape and organization of the dispersed units are expected to influence the mechanical properties. We may add that in the case of a macroscopic "crystal" we would expect a pronounced directionality in property. Accordingly we should have an anisotropic elastomer, adding another significant factor influencing the mechanical properties.

Perhaps the major question is the origin of the forces which keeps the *S* particles in their exact lattice position. We suggest that on average the two *S* blocks of a given chain are situated in two different cylinders. Accordingly, the cylinders will be molecularly connected by *B* blocks which, being in a rubbery state, will act as an entropy spring. The different molecular springs connecting a given cylinder to its neighbours will be in different degrees of tension or compression depending on the end-to-end separation of the appropriate *B* block, and the cylinder will take up the position which minimizes these forces. This condition then defines the lattice. Accordingly we should have a situation where the lattice forces are represented by true material springs.

Field Emission from Silicon Carbide Whiskers

It is thought that most of the silicon carbide whiskers grown by the E.R.D.E. process do so by the vapour–liquid–solid (VLS) mechanism[1] where a metal is the principal "activator" in the process. Often a globule of frozen eutectic can be seen on the ends of the whiskers. Further, it has been observed that in many cases smaller whiskers had grown out from these balls. Some of the specimens, however, did not show such a eutectic residue on their ends and it is these that have been studied here.

The field emission microscope is ideally suited for the examination of the ends of these semiconducting needles. Not only is a highly magnified image of the whisker tip produced, but also it is possible by application of the equations describing the emission from semiconducting surfaces[2–4] to calculate the impurity concentration within the lattice, and further, by field evaporating the atoms from the whisker end, to measure the level of impurity down the whisker length. These results should therefore yield the amount of contaminant, presumably metallic, that is being deposited within the crystal lattice.

The whiskers used were 2–5 microns in diameter and were fastened to a typical field emission filament array with aquadag. Because we were interested in examining the whiskers as grown, the ends were not etched down to fine points as is the normal practice[5–7]. Two probe leads, spot welded to the heater filament for monitoring the temperature of the heater loop, were connected to a Kelvin bridge network[8]. This was calibrated at 77 K and room temperature, and at higher temperatures with an optical pyrometer. The microscope was connected to a typical UHV line which was pumped by a 50 ls^{-1} diffusion pump and a 10 ls^{-1} ion pump to pressures of 3 to 5×10^{-10} torr. Current–voltage characteristics were monitored rapidly and automatically by the previously described system[9].

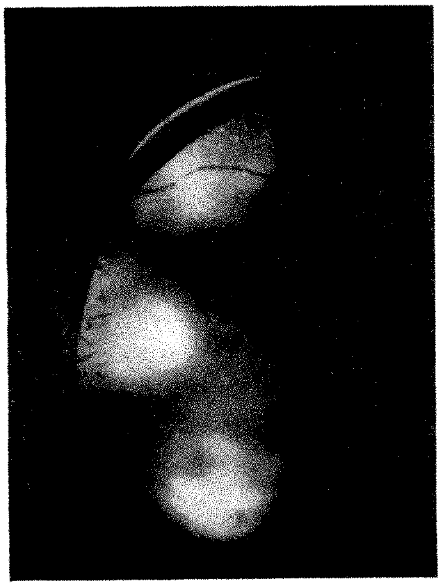

Fig. 1. Typical emission pattern from an unetched SiC whisker. Applied voltage 3 kV.

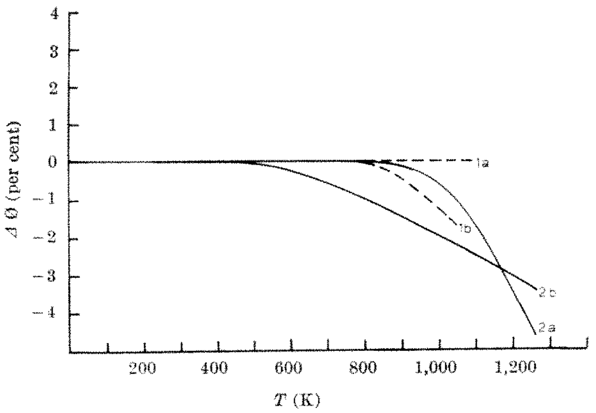

Fig. 2. Change in work function with temperature at a fixed applied voltage for two whiskers; 1a and 2a before field evaporation, 1b and 2b after field evaporation.

A typical field emission pattern obtained at an operating voltage of 3 kV is shown in Fig. 1. In view of the low voltage applied and the fact that the whisker is 2 microns in diameter, it is likely that these patterns originate from small projections present on the surface of the whisker tip. A closer examination of such images revealed that there was a degree of overlap in the patterns and in certain cases there was evidence of four-fold symmetry indicative of a cubic structure which indeed silicon carbide can possess.

These observations seem to indicate that the projections might be, indeed, "microwhiskers" analogous to those seen on the whiskers with a ball of eutectic on their ends. Experiments being carried out in which the tip is progressively removed by field evaporation should help to clear up this point.

The current–voltage characteristics of the emitter–anode diode were measured for a temperature range of 77 K to 1,200 K. The percentage change in work function with temperature was calculated from the ratio of the slopes of the Fowler–Nordheim equation at the different temperatures to that at room temperature, Fig. 2. It should be pointed out that for a given temperature the equation was obeyed well and only deviated markedly in the 1,200 K region.

In certain cases (for example, whisker 1a, Fig. 2), the work function did not change at all, even up to 1,200 K, and the Fowler–Nordheim equation was obeyed very closely indeed. With others (for example, whisker 2a, Fig. 2), the work function remained constant with temperature only up to some critical value, after which it changed in the manner depicted. It is therefore clear that the emission of the electrons is temperature dependent and this

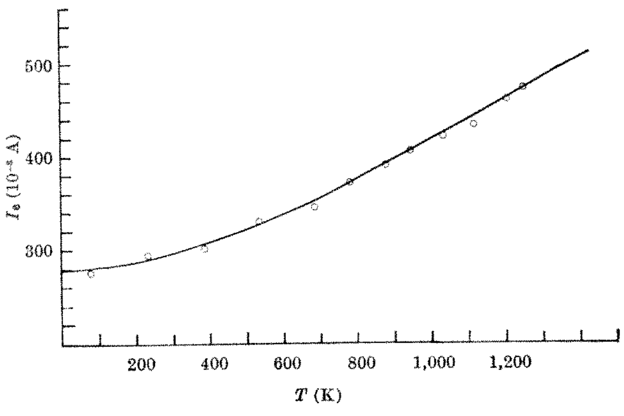

Fig. 3. Current versus temperature plot for whisker 2b. Applied field constant.

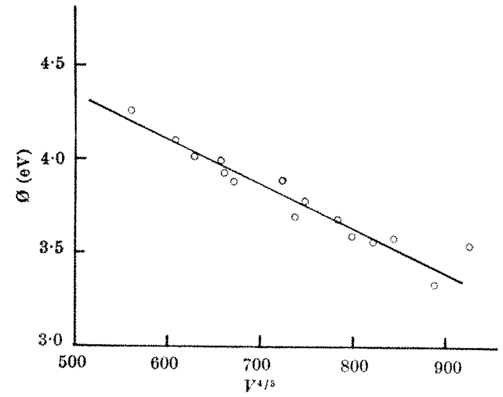

Fig. 4. A plot of work function against $V^{4/5}$, showing that field penetration has taken place.

relationship of emission current with temperature is plotted in Fig. 3 for whisker 2b.

These results lead to the conclusion that the electrons are being emitted from the conduction band and that the whisker is behaving as an n-type semiconductor. This being so, then from the equations given by Stratton[2,3] and Gomer[4] it should be possible to calculate the number of electrons in the conduction band and hence the concentration of impurity donor atoms in the lattice. On attempting to do this, however, it was found that the experimental current–temperature relationship did not comply with the theoretical equations. At this stage, therefore, it has not been possible to calculate the contamination level. It has been possible, however, to demonstrate that there is a gradation of properties down the shanks of the "microwhiskers", for on field evaporation the temperature dependence changed as shown in curves 1b and 2b of Fig. 2. The curve 1a to 1b can be interpreted qualitatively to mean that the whisker tip was highly contaminated, perhaps originally metallic, in character, but on field evaporation this metal was removed and the whisker began to demonstrate semiconducting properties. Similarly with curves 2a and 2b there is a change from a contaminated to a less contaminated whisker. It would seem therefore that the concentration of impurity atoms, possibly the metal from the eutectic, is decreasing down the shank of the "microwhiskers".

It has been assumed, from the observations made here, that the "microwhiskers" are behaving as n-type semiconductors with emission occurring from the conduction band. If this assumption is correct, then not only should there be a temperature dependence but also a field dependence should become evident. If the field is increased to such an extent that field penetration becomes so great that the conduction band edge is depressed well below the bulk Fermi-level, then Fermi–Dirac statistics apply. In such a case the Fowler–Nordheim equation holds with the correction that the observed work function φ_m is given now by

$$\varphi_m = \varphi_0 - A V^{4/5}$$

where φ_0 (4·2 eV)[10] is the depth of the conduction band, A is a constant involving the dimensions of the whisker and its dielectric constant, and V is the applied voltage. Experiments were performed to test this condition. As shown in Fig. 4 the relationship was obeyed, and strongly supports the assumption derived from the current–temperature observations.

The observations are consistent with the idea that small projections or "microwhiskers" are present on the tip of whiskers which do not possess a little ball of frozen eutectic on their ends and that these "microwhiskers" are behaving as n-type semiconductors. There is also a decrease in the concentration of impurity atoms down the shank of these projections. Because there is a discrepancy between experiment and theory, the degree of contamination could not be estimated. This anomaly could be a result of the contamination being excessively high and/or the band structure in these very tiny crystals differing markedly from those assumed in the theoretical calculations.

In conclusion, the experiments have shown that the end structure, observed on the macro-scale in many cases, consisting of smaller whiskers growing out of the eutectic ball, exists on a micro-scale for the whiskers examined here. It has become apparent also that an estimation of the impurity content within the microwhiskers cannot be made. More work on the temperature relationship of the emission current for both the microwhiskers and etched whiskers will have to be carried out to clarify this situation. Such an estimation of the impurity content would help to give a better understanding of the growth mechanism.

I thank D. Henshaw and A. R. Osborn for their helpful discussions.

Ribbed Growth of Graphite in Ni-C Solutions containing Boron

WE report here on some effects due to boron in Ni-C melts. A number of interesting and hitherto unnoted features of graphite growth have been observed. The significance of these observations is that they demonstrate

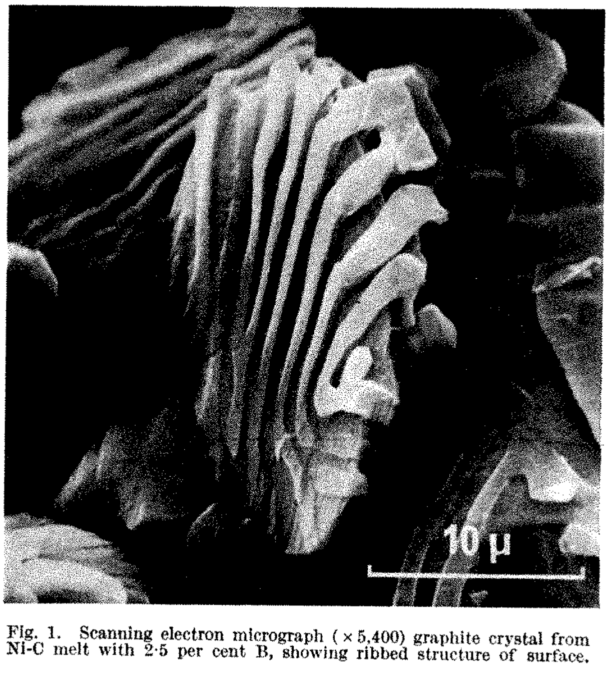

Fig. 1. Scanning electron micrograph (×5,400) graphite crystal from Ni-C melt with 2·5 per cent B, showing ribbed structure of surface.

an important mechanism of a morphology change in graphite growing from solution. We show that the growth changes can be attributed to a concentration of boron in a boundary layer at the liquid-solid interface. Growth interfaces break down and morphology changes result. In particular, we have observed both scroll and spherulitic forms.

In previous investigations in the Ni-C system, the growth of dendritic graphite[1] and effects resulting from the interaction between lanthanum and growing graphite[2] were described. In the present experiments, we have noted completely new effects when boron is added to Ni-C solutions.

The experiments we carried out used pure nickel and boron added as nickel boride. The nickel was melted in graphite crucibles by induction heating, under an atmosphere of CO and equilibrated with the carbon of the crucible for 5 min at 1,550° C. Pure nickel boride was then added in each experiment in amounts to give melt concentrations of 0·25, 0·5 and 2·5 weight per cent boron. The melt was stirred and retained at this temperature for 3 min before cooling. Freezing rates in the solidification range were approximately 45° C/min.

The ingots were sectioned and one half of each specimen was prepared for metallographic examination. Sections taken from the second half were dissolved in dilute HCl to obtain separated graphite crystals for examination by scanning electron microscopy. These crystals were coated with a thin evaporated gold film and examined in the normal manner with a Cambridge 'Stereoscan' instrument.

The metallographic examination showed a gradual reduction in the graphite content as the boron concentration increased. At the same time, a non-graphitic eutectic phase increased in volume.

A specimen structure of a graphite crystal observed in the scanning electron microscope is shown in Fig. 1. It shows ribbed steps developing on the crystal surface. This structure, which initiated at small boron concentrations, was observed to accentuate with increasing boron and, in the highest boron content alloy (2·5 weight per cent B), ribs grow independently from the crystal surface into the melt. Crystals of this character are shown in Fig. 2. The dimension of these ribs is approximately 0·5 microns in cross-section.

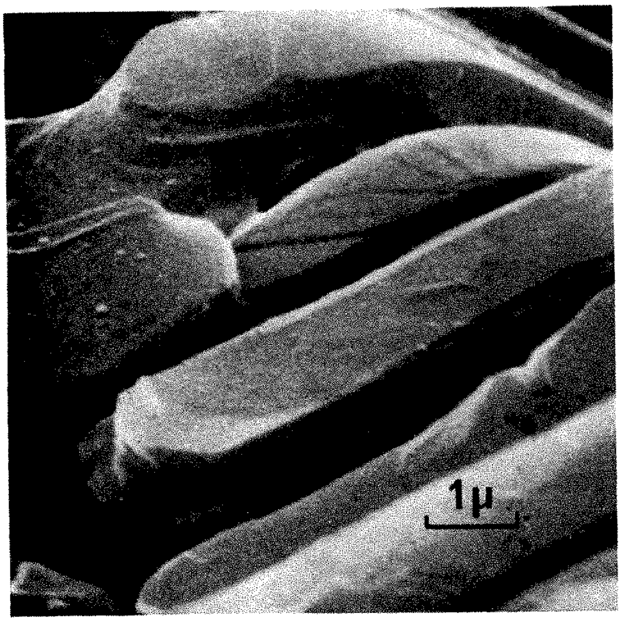

Fig. 2. Scanning electron micrograph (× 46,000). Ribs of graphite growing from crystal surface.

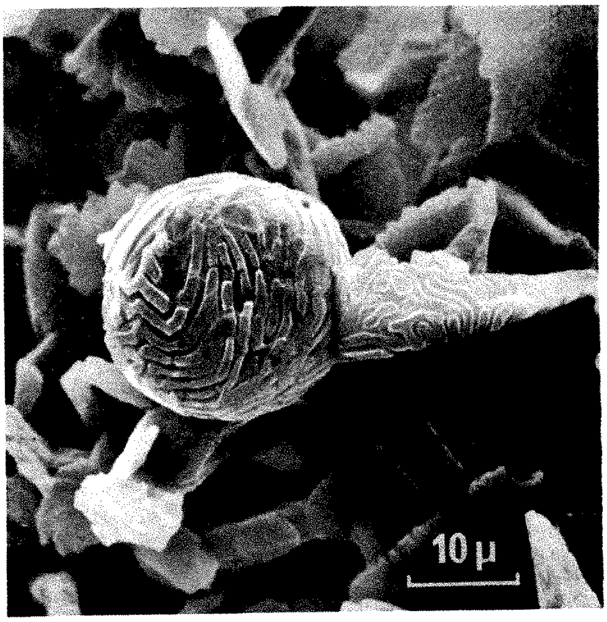

Fig. 3. Scanning electron micrograph (× 5,400). Spherical crystal of graphite joined to crystal of scroll type.

Two types of crystal other than flake were noted. These were in the forms of sphere and a scroll. Fig. 3 shows a spherical crystal joined to one of scroll type.

The experimental evidence is that the ribbed growth is due to the boron in solution and the ribs are formed in the following manner. Steps, which normally traverse the crystal surface along plane fronts, break down to form step protuberances which eventually dominate the growth. The concentration of 2·5 weight per cent B at which the increasing change in growth characteristics occurs is far in excess of normal growth poison effects[3]. This suggests that boron forms a solute boundary layer at the growing graphite interface (due to its low solubility in graphite) which produces a breakdown of step movement on its surface. All forms observed grow ribbed, whether plate, sphere or scroll. The ribbed crystals have a remarkable ability to adopt curved geometries.

It is of interest to compare the action of boron and its effect on graphite with the previously observed effect of lanthanum[2]. The latter element has a pronounced effect at a melt concentration of approximately 0·01 weight per cent La. Its specific action is to block the movement of a growth step by physical adsorption at the step. This might be expected of an element in the metallic solution which is very reactive with the carbon at this temperature. It has been noted that the melt, if the adsorbing element is present, has to undercool for further growth to occur[2] and this growth is then accentuated in the direction normal to (0001) planes. In the case of boron, the solute is rejected in the melt and swept ahead of the interface. Step growth on crystal surfaces is principally as protuberances in the (0001) plane. When the boron content is sufficiently high, these protuberances dominate growth.

A comparative effect in polymer growth, discussed by Keith and Padden[4], termed "fibrillation" has been described as having origin in causes similar to those described here. The planar interface solidification which leads to plate forms breaks down due to impurity concentration at a boundary layer. The grooves formation leads to needle like growth forms.

Fibrillar spherulites in polymers grow from a centre and branch outwards. The fibril of graphite growing in the presence of boron, however, is observed to grow circumferentially round the sphere. In both the case of polymer growth and graphite growth with boron, the action of the impurity is similar in that planar interface growth is prevented and crystals of a different geometry can then grow.

It is of interest to recall that scroll forms of graphite were observed by Bacon[5], growing in boules from arced carbon electrodes. The scroll forms observed here growing in solution do not develop from one continuous sheet as in the special case noted by Bacon, but grow from a series of ribs which develop over the crystal surface.

Magnetic Relaxation in Ordered Systems

NUCLEAR magnetic resonance (NMR) spectroscopy is one of the most promising techniques to be recently applied to the study of lipid, protein and water interactions in biological and other ordered and semi-ordered systems. NMR studies of the water in many hydrated biological systems have been interpreted in terms of the existence of "structured", "ice-like" or "bound" water[1-6]. Likewise, line broadening in ordered liquid crystalline and biological systems has often been taken as an indication of restriction of molecular motion[7-13]. We should like to point out some possible pitfalls in interpreting the results of limited relaxation or line width data in terms of changes in molecular mobility arising from specific interactions, in systems which are not isotropic liquids and are not always homogeneous. We have carried out a spin-echo NMR study of the dimethyldodecylamine oxide–deuterium oxide system—a system in which anisotropic ordered structures exist and one for which considerable X-ray and continuous wave NMR data are available[9,14]. This system is an ideal one for the study of the effects of molecular ordering and anisotropy on the measured NMR parameters because the structure can be changed from isotropic to anisotropic simply by a slight change in composition or temperature.

In this system, high resolution NMR lines are observed for both the surfactant and water in the micellar and the cubic (viscous isotropic) phases, and much broader, non-Lorentzian lines are observed for the surfactant in the anisotropic hexagonal (middle) and lamellar (neat) phases[9]. The lines from the ^2H_2O in the anisotropic structures manifest residual quadrupolar coupling[9]. The line broadening and line shape for surfactant protons in the anisotropic phases were attributed by Lawson and Flautt[9] to a decrease in the rate of molecular reorientation and to the existence of a distribution of correlation times describing the reorientation processes. Penkett *et al.*[15] have attributed the line broadening observed in similar anisotropic systems —potassium laurate in ^2H_2O and lecithin in ^2H_2O—to the existence of a "magnetic anisotropic effect". They cite the observed magnetic field dependence of the line width and the decrease in line width produced by sonication as evidence for this effect. Thus they interpret the line broadening as resulting from the structure of the mesophase rather than from the rate of molecular reorientation. More recently, Sheard questions the interpretation of the sonication experiments[16]. He believes that the changes in line width result from a change in internal structure produced by the ultrasonic irradiation. The results we present here are pertinent to the interpretation of the line broadening observed at the isotropic–anisotropic phase transitions in liquid crystalline systems and have significance for studies carried out on other ordered, anisotropic, non-homogeneous systems.

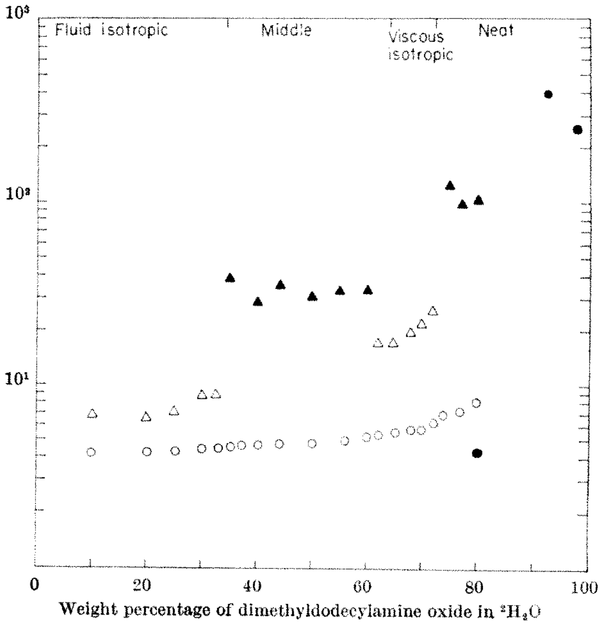

Fig. 1. Spin–spin and spin–lattice relaxation rates for surfactant protons as a function of weight per cent dimethyldodecylamine oxide in ^2H_2O. △, R_2; ▲, R_2(eff.), defined in text; ○ R_1.

Sample preparation has been described elsewhere[14]. Relaxation data were obtained on a Magnion ELH-15 pulsed spectrometer, operating at 36 and 6 MHz and equipped with a Varian 12 inch electromagnet with flux stabilizer. Both spin–spin and spin–lattice relaxation rates, $R_2(=T_2^{-1})$ and $R_1(=T_1^{-1})$, respectively, were measured. R_2 is a more direct and easily interpretable measure of the magnetic interactions, in a system in which the absorption line shape is neither Lorentzian nor Gaussian, than is the line width, and R_1 is a measure of the rate, and the distribution of rates, of molecular reorientation. The measurements of R_2 were made using the Carr–Purcell method[17] as modified by Meiboom and Gill[18]. The R_1 values were obtained by means of repeated 180°–90° pulse sequences[17] but from the slope of a semilog plot of the magnetization recovery rather than from a visual estimate of the null[19].

The proton relaxation rates R_1 and R_2 observed for dimethyldodecylamine oxide as a function of concentration in ^2H_2O are shown in Fig. 1. Discontinuities in the R_2 plot are observed at the phase boundaries, R_2 being much larger in the anisotropic than in the isotropic phases. Single exponential relaxation (one relaxation time) is observed for both R_1 and R_2 in the isotropic phases but only for R_1 in the anisotropic phases. The observed "effective" R_2 value in the anisotropic phases, R_2(eff.), is defined as the time at which the transverse magnetization has decayed to e^{-1} times the thermal equilibrium value. If the spin–spin relaxation were exponential, then R_2(eff.) $=R_2$. The observation that $R_2 \approx R_1$ in the isotropic phases is typical of liquids with isotropic molecular motion[20] and is consistent with the observation of high resolution NMR spectra for these phases[9]. In the anisotropic phases the spin–spin relaxation is non-exponential and $R_2 \gg R_1$. If in these phases, the non-Lorentzian line shape results from a distribution of correlation times, as suggested[9], the spin–lattice relaxation should also be non-exponential[21,22]. This is not observed, so that other explanations must be sought

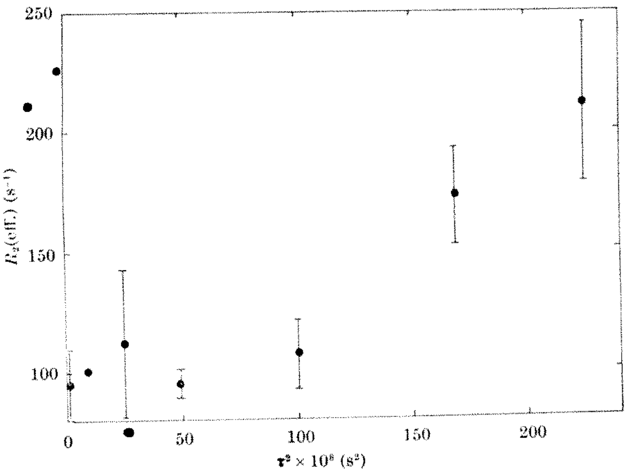

Fig. 2. Spin–spin relaxation rate for surfactant protons as a function of the Carr–Purcell pulse spacing, τ. The sample is 77 per cent by weight dimethyldodecylamine oxide in ^2H_2O (neat phase). The vertical lines through each point represent the r.m.s. errors.

for the line shape and relaxation data. The observations that R_1 has no discontinuities at the phase boundaries and remains essentially constant throughout the phases indicate that the rate of those molecular motions contributing to R_1 (probably hydrocarbon chain oscillations) does not change appreciably with concentration or with phase structure. Thus it seems that the changes in R_2 and in line width are not produced solely by changes in molecular motion. Evidently there is another relaxation mechanism operating in the anisotropic phases which contributes to R_2 but not to R_1, results in $R_2 \gg R_1$, and is responsible for the non-Lorentzian line shape.

In the anisotropic phases there is an observed dependence of R_2, for both the surfactant protons and the deuterium nuclei in the ^2H_2O, on the pulse spacing (τ) in the Carr–Purcell experiment[17]. Fig. 2 shows the proton R_2 as a function of τ^2 for a 77 per cent dimethyldodecylamine oxide–33 per cent ^2H_2O sample (neat phase). A similar dependence of R_2 on τ is found in the middle phase, but not in the isotropic phases. This dependence of R_2 on τ indicates the existence of another relaxation mechanism in addition to the dipolar relaxation resulting from molecular reorientation. There are two possible reasons for the τ dependence. It could be produced by exchange[23] of surfactant molecules between aqueous and hydrocarbon portions of the mesophase; but because R_2 is essentially independent of water content in a given phase this is apparently not the reason. The second and most likely reason is molecular diffusion. When relaxation is the result of molecular diffusion through magnetic field gradients, R_2 will be a linear function of τ^2 and will be greater than R_1. This phenomenon is the basis of the Carr–Purcell method of measuring self-diffusion coefficients using externally applied magnetic field gradients[17,24]. Spin–spin relaxation resulting from molecular diffusion through local magnetic field gradients produced by the microscopic heterogeneity of the sample has been observed for lithium in liquid dispersions[25], for benzene dissolved in solutions of high molecular weight polymers[26], and in binary solutions at their critical temperature[27]. If the structures of the anisotropic phases result in a "solution" of sufficient microscopic inhomogeneity, it is possible that diffusion of surfactant molecules through these regions could give rise to the relaxation data observed here and also to the "magnetic anisotropic effect" of Penkett *et al.*[15]. This inhomogeneity could result from orientation of large regions in different directions with respect to the applied field. The observed dependence of R_2 on τ^2 is not quite linear. This nonlinearity could result from the presence of a distribution of field gradients and from the fact that diffusion is restricted and anisotropic.

Field gradients resulting from magnetic susceptibility differences are field dependent and should increase with increasing applied field. If diffusion through the gradients contributes to the relaxation, then R_2 would be expected to increase with increasing field. Penkett *et al.*[15] have reported that the line widths of lamellar phases do increase with increasing field. Table 1 shows the field dependence of R_2 for a neat phase sample of dimethyldodecylamine oxide. R_2(eff.), previously defined, is measured by the Carr–Purcell method[17] with $\tau = 100$ μs (the shortest pulse spacing obtainable with our equipment). This method removes the effects on R_2 of molecular diffusion through field gradients. Thus if diffusion through field gradients is responsible for the anisotropic phase relaxation behaviour and for the observed[15] field dependence of line widths in lamellar phases, it is expected that the R_2 values measured by the Carr–Purcell method would be independent of the applied magnetic field strength. This is seen to be so, within experimental error, from the data in Table 1. R_2^*(eff.) is defined like R_2(eff.), except that it is measured from the free induction decay. By contrast with the Carr–Purcell method, this experiment gives R_2 values which reflect diffusion effects[17]. It is expected therefore that R_2^*(eff.) would increase with increasing applied field, which is so. Diffusion through local field gradients therefore seems to be partially responsible for the relaxation in the anisotropic phases, and these effects can be removed if a sufficiently small τ is used. The non-Lorentzian line shape in these phases seems consistent with the relaxation data; the absorption spectrum of a system whose spin–spin relaxation is non-exponential will be non-Lorentzian[28]. That this is not the only relaxation mechanism contributing to R_2 is indicated by the fact that even in the Carr–Purcell experiment with a τ of 100 μs the spin–spin relaxation is not completely exponential and by the fact that extrapolation of the data in Fig. 2 to $\tau = 0$ results in an R_2 that is larger than R_1. Further studies are being undertaken to determine the nature of these other relaxation mechanisms, which may involve anisotropic molecular reorientation.

Table 1. SPIN–SPIN RELAXATION RATES

H_0 kG	R_2^*(eff.), s^{-1}	R_2(eff.), s^{-1}
1·409	4,300 ± 350	126 ± 30
8·459	10,800 ± 900	95 ± 15

Measurements were made at two magnetic field strengths for surfactant protons in the 77 per cent dimethyldodecylamine oxide in ^2H_2O system (neat phase). R_2^*(eff.) and R_2(eff.) are defined in the text.

This study indicates the complexity of the relaxation processes in non-isotropic systems and points out the possible dangerous ambiguity which could be contained in interpretations based solely on line width measurements or on incomplete relaxation data. In systems like the lyotropic mesophases and in macromolecular biological systems it is possible that the diffusion of water, or other molecules, through microscopic inhomogeneities in the samples may result in line broadening and an increase in R_2, thus leading to erroneous conclusions about molecular mobility. Studies of such systems by NMR should include experiments along the lines we have used.

Dye Lasers in the Ultraviolet

POTENTIAL applications of dye lasers in the fields of air pollution monitoring, photochemistry and biology have stimulated interest in operating dye lasers in the spectral region below 4500 Å. Many important molecular resonances and reaction thresholds are found at these higher photon energies. Using an AVCO C950 pulsed N_2 gas laser, with its output at 3371 Å in the ultraviolet, we have been able to obtain continuously tunable dye laser action as low as 3550 Å. This pumping technique has been described in some detail elsewhere[1]. The present scheme has a transverse pumping configuration where the rectangular N_2 laser beam is focused to a line within the dye cell and the dye laser's optical cavity. The pumping laser is capable of 100 kW peak power in a 10 ns pulse duration, and can be pulsed at rates as high as 100 pulses per second[2]. In the visible region of the spectrum, this system has produced dye laser peak powers as high as 30 kW and repetition rates up to 100 pulses s^{-1}. It is also significant that the visible dyes have attained these repetition rates in sealed dye cells without any external dye circulation.

In transverse pumping, the laser cavity and resulting dye laser beam are at right angles to the direction of propagation of the laser pump. With the N_2 laser, the dye gain is usually very large and superradiant oscillation is frequently observed. The output mirror of the cavity was a metallic coated, spectrally flat (57 per cent ± 2 per cent) transmitting mirror and the "high reflectivity" end was a diffraction grating. The grating enables one to tune the frequency of the laser selectively, and it also has the advantage that it can be used to "frequency pull" the response of a dye to wavelengths beyond the observed natural fluorescence of the dye[3]. The output pulse of the dye laser was monitored with an ITT F4000 photodiode with an S–5 spectral response and the wavelength response was measured with a Jarrell–Ash 0·5 m monochromator with an S–20 photomultiplier.

Table 1

Dye	Solvent	Spectral range
αNOPON	Benzene	4300–4550
POPOP	Tetrahydrofuran	4150–4300
Diphenylanthracene	Ethanol	4350–4500
Diphenyl stilbene	Toluene	4000–4150
	Benzene	4000–4150
αNPO	Benzene	3975–4100
	Cyclohexane	3850–4150
Sodium-salicylate	Ethanol	3950–4180
BBO	Ethanol	3640–3850
PPF	Ethanol	3650–3710
PPD	Ethanol	3830–3950
PBD	Ethanol	3550–3820
Aminobenzoic acid	Toluene	3980–4060
BOPOB	Tetrahydrafuran	4280–4500
p-Quaterphenyl	Toluene	3620–3900
BBP	Benzene	4000–4150

Table 1 is a list of the dyes and scintillators that have been observed to lase below 4500 Å, together with the solvents in which they were dissolved and the spectral range over which they could be made to lase. This information is also shown schematically in Fig. 1.

It should be pointed out that our search with a low Q optical cavity selected those dyes in which superradiant or near superradiant gain was obtainable. Other violet fluorescing compounds that we pumped but were unable to make lase with our present system and cavity optics were 4-dimethylamino antipyrine, 1-naphthylamine, and quinine sulphate.

Many of the absorption and fluorescence spectra of the above compounds are given by Bearlman[4]. Despite the fact that the reported absorption peaks of naphthylamine and quinine sulphate almost coincide with the pumping wavelength at 3371 Å, with high reported fluorescence efficiencies, we are unable to make these compounds lase. On the other hand, PPD and PBD are two compounds with absorption bands several hundred Ångstroms removed from 3371 Å, but they lase quite readily. Dye molecular limitations, such as low molecular extinction coefficients, slow excited singlet state relaxation rates, long spontaneous emission lifetimes or losses to the triplet states by radiationless transitions, may prevent the two former compounds from exhibiting high gain at any wavelength with the present N_2 laser pumping. Un-

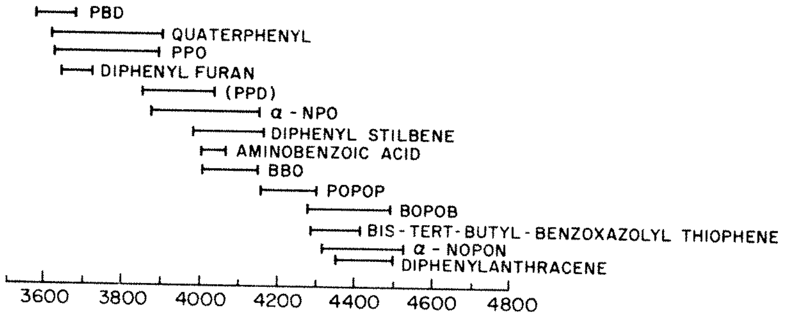

Fig. 1. Effective lasing ranges of dyes in the violet.

ambiguous interpretation of the relative importance of these effects would be extremely difficult without further molecular data. The fact that compounds such as PPD, which are not even expected to absorb 3371 Å radiation, show high gain suggests that dimers or excimers that absorb 3371 Å radiation may be forming in solution and lasing themselves, or their decomposition fragments may lase. This speculation is supported by the observation that some compounds, such as PPD or sodium salicylate, will only lase at quite high solution concentrations greater than 10^{-3} moles/l.

Solvents were included in the table of dyes, because the proper solvent determines, in many cases, whether or not a dye will reach lasing threshold. The effect of the solvent on lasing ability may be closely related to the singlet–triplet transition rate, which may be the limiting step in attaining threshold.

The ultraviolet dyes below 4000 Å are usually less efficient, and lase in a narrower spectral range than the visible dyes. Between 4000 and 4500 Å, conversion efficiencies of the order of 15–20 per cent have been obtained, while below 4000 Å the efficiencies so far obtained have been of the order of 1 per cent or less. Effective spectral ranges in this region are, on the average, of the order of 100–150 Å, while the visible dyes have in some cases spectral ranges as broad as 500–600 Å. Another disadvantage of a few ultraviolet dyes is that they have limitations on the rate at which they can be pulsed in our non-flowing dye cell. This indicates that these dyes may be decomposing (such effects were not observed for the visible dyes studied), and they must either flow or be cooled to perform as well as their visible counterparts.

While this list of scintillators and dyes is not complete, our success does indicate that tunable dye laser action is feasible down to, and probably well below, 3500 Å. We are continuing this work in order to improve ultraviolet dye laser performance.

BIOLOGICAL SCIENCES

Changes in Nucleoside Conformation

Arnott and Hukins[1], and Sundaralingam[2], have recently compared the conformational parameters of nucleosides and nucleotides with those found in polynucleotide structures. Two of the parameters they discuss are the relative orientation of the sugar component with respect to the purine or pyrimidine base, and the type of pucker in the sugar ring.

I should like to draw attention to the variation of these two parameters in three nucleosides that have been studied in this laboratory. The three nucleosides are 5-bromouridine, inosine and 5-iodouridine, and they are of interest because they show differences in conformation when in different environments in a crystal. The structure of 5-bromouridine has been determined when it is complexed with adenosine[3]; when it crystallizes by itself[4]; and when it is complexed with dimethylsulphoxide[5]. Inosine has been studied in two crystal forms[6-9], and in the case of 5-iodouridine there are two molecules in the asymmetric unit which have markedly different conformations[10].

The relative orientation of the sugar and base may be described in terms of a torsion angle φ_{CN} (ref. 11), or an angle χ (ref. 1), and, like most nucleosides, the three discussed here are in the *anti* conformation. Also, the pucker of the sugar rings is either C2′ *endo* or C3′ *endo*, the most common type of pucker observed in nucleosides and nucleotides.

Haschemeyer and Rich[12] have calculated the "allowed" ranges of φ_{CN} in nucleosides with different puckers, based on a consideration of intramolecular contacts. These calculations show that the *anti* ranges for both C2′ *endo* and C3′ *endo* pyrimidine nucleosides are not very different, and, although the ranges are larger for purine nucleosides, again the allowed ranges for C3′ and C2′ *endo* puckers are similar. It is therefore surprising to find, even in the three nucleosides discussed here, that the mean value of the φ_{CN} angles for the C3′ *endo* pucker has a smaller magnitude than the mean value of φ_{CN} for those with a C2′ *endo* pucker. This result is in agreement with the conclusion of Arnott and Hukins[1], based on a survey of nucleosides and nucleotides, and also that of Sundaralingam[2]. The φ_{CN} values are given in Table 1. The mean φ_{CN} value for the C2′ *endo* pucker is −69° and for the C3′ *endo* pucker it is −15°. In the refined molecular models of B-DNA and A-DNA structures[13] the φ_{CN} values are −80° and −19° respectively; in B-DNA the pucker is C2′ *endo* and in A-DNA it is C3′ *endo*. Thus the changes in the environments of the nucleosides in the crystal bring about similar changes in conformation to those occurring when DNA changes from one form to the other. Although there is this apparent correlation between the type of pucker and the mean value of φ_{CN} in nucleosides, there is an overlap of the ranges of the φ_{CN} values for the two types of pucker as may be seen from Table 1 of Haschemeyer and Rich[12].

Table 1. CONFORMATIONAL DATA ON NUCLEOSIDES

Nucleoside	φ_{CN}	Pucker	Ref.
Bromouridine			
Bromouridine + adenosine	−20°	C3′ *endo*	3
Bromouridine	−56°	C2′ *endo*	4
Bromouridine + dimethylsulphoxide	−63°	C2′ *endo*	5
Inosine			
Molecule I	−10·6°	C3′ *endo*	6, 7
Molecule IIA	−121°	C2′ *endo*	8, 9
Molecule IIB	−45°	C2′ *endo*	8, 9
Iodouridine			
Molecule I	−13°	C3′ *endo*	10
Molecule II	−59°	C2′ *endo*	10

I thank Dr Struther Arnott for showing me a draft of his manuscript with D. W. L. Hukins before publication, and Dr P. Tollin for discussion.

Electron Reactions in γ-Irradiated Thymidine and Cystamine

ALTHOUGH the technique of electron spin resonance (ESR) has been useful in the identification of some of the secondary radical species formed in γ-irradiated DNA and proteins, difficulties have been experienced in the interpretation of the spectra of the primary radiolytic products. Two of these secondary species are the thymine radical (with an additional H-atom on C-6 of the thymine ring) in DNA (refs. 1–3) and the radical R—CH$_2$—S$^\cdot$ in cystine-containing proteins[4–6]. Both have been postulated to be the result of electron reactions[7–10]. We have irradiated two model compounds, thymidine and cystamine, in frozen glasses of either ethanediol–water (1 : 1) or 6 M NaOH and, by comparing the ESR and optical absorption spectra, we have identified the anions produced.

All solutions were degassed and irradiated at less than 90 K with ^{60}Co γ-rays. Measurements were made in the dose range 0–400 krad. The first derivative ESR spectra were recorded at 77 K using a conventional X-band spectrometer[8]. Optical absorption spectra were recorded at about 90 K on an *SP*800 spectrophotometer using a spectrodewar similar to that described by Simons[11] and supplied by Jencons Ltd, England. All the spectroscopic details are summarized in Table 1.

Table 1. SPECTROSCOPIC DETAILS OF THE SPECIES OBSERVED IN γ-IRRADIATED GLASSES

Species observed	ESR g	N	Optical absorption λ_{max}	$G\varepsilon_{max}$	ε_{max}	Pulse radiolysis at room temp. in H$_2$O λ_{max}	ε_{max}	Ref.

* Unpublished work of E. M. Fielden and G. Stevens.

† At *p*H 13·5.

‡ Measured after 10 min ultraviolet irradiation ($\lambda > 310$ nm).

g: g value of ESR spectrum; N: number of lines in ESR spectrum; λ_{max}: wavelength (in nm) of maximum optical absorption; G: number of species formed by 100 eV of absorbed radiation which can be calculated from the ESR data; ε_{max}: extinction coefficient at λ_{max}. In 6 M NaOH, thymidine is in the ionized form, which accounts for the shift in the absorption maxima of T$^-$ and TH$^\cdot$. A similar effect has been observed with the OH radical adduct of thymine in pulse radiolysis studies[17]. ε_{max} is calculated using G values taken from the ESR work. Quoted absolute radical yields vary considerably from one laboratory to another. Relative errors in the values of ε_{max} are ±10 per cent; the absolute errors are ±30 per cent.

In the absence of solutes the ESR spectrum of an irradiated ethanediol-H$_2$O glass consisted of a sharp singlet ($g = 2·001$) (from the trapped electron, e_t^-) (refs. 12, 13) superimposed on a triplet. Bleaching of the e_t^- caused it to react with the ethanediol to give an increase in the triplet spectrum. In the presence of 0·05 M cystamine the yield of e_t^- was reduced to 43 per cent although the yield of the triplet was unchanged. There was a new broad singlet in the ESR spectrum at $g = 2·01$ with an associated optical absorption at 395 nm. Bleaching e_t^- with white light did not affect this new absorption. The ESR spectrum of the free radical R—CH$_2$—S$^\cdot$ which has been observed in many irradiated sulphur compounds (see, for example, references 5, 10 and 14) was absent. The species observed in these studies was formed at the expense of e_t^- and we can therefore conclude that it is the cystamine anion, the high g value indicating that the electron is localized on the disulphide bond.

In the presence of 0·08 M thymidine, the yield of e_t^- was reduced to 10 per cent and a new optical absorption was observed at 320 nm. The ESR spectrum contained a doublet with a hyperfine splitting of 15 G together with a small trace of an eight line spectrum superimposed on the triplet from ethanediol (the yield of which was again unchanged by the presence of the additive). White light bleaching removed e_t^- with no noticeable effect on the other species, whereas on irradiation with ultraviolet light (wavelengths above 310 nm) the doublet disappeared and at the same time there was a large increase in the eight line ESR spectrum which has been identified as the thymine radical (TH$^\cdot$) (ref. 3). Comparison of the ESR and optical data showed that this radical had an absorption maximum at 410 nm. The doublet ESR spectrum together with the optical absorption at 320 nm must be attributed to the thymidine anion (*T*$^-$) because its formation leads to a large reduction in e_t^-.

Examples of spectra obtained in 6 M NaOH glasses are shown in Figs. 1 and 2. The ESR spectrum of a γ-irradiated 6 M NaOH glass revealed a sharp singlet at $g = 2·001$ superimposed on a broad doublet centred at $g = 2·05$. These spectra arise from e_t^- and O$^-$, respectively[12,13,16]. The addition of 0·08 M thymidine reduced the yield of e_t^- to 6 per cent and increased the yield of O$^-$ to 135 per cent. With ESR we observed the additional spectra of T$^-$ (a doublet) and TH$^\cdot$ (eight lines) (Fig. 1). The corresponding optical absorption spectra had maxima at 330 nm and 470 nm (Fig. 2). The 6 M NaOH glass was different from polycrystalline water[8] and ethanediol–H$_2$O glass, in that there was a large yield of TH$^\cdot$ immediately after irradiation. Removal of e_t^- with white light had no observable effect on the other species present. Subsequent irradiation at ultraviolet wavelengths above 310 nm removed T$^-$ (330 nm absorption and ESR doublet) and increased the yield of TH$^\cdot$ (470 nm absorption and ESR octet). For purposes of comparison, the absorption maxima and optical extinction coefficients for the same species observed in aqueous solution at room temperature are given in Table 1. These data have been obtained by others using pulse radiolysis.

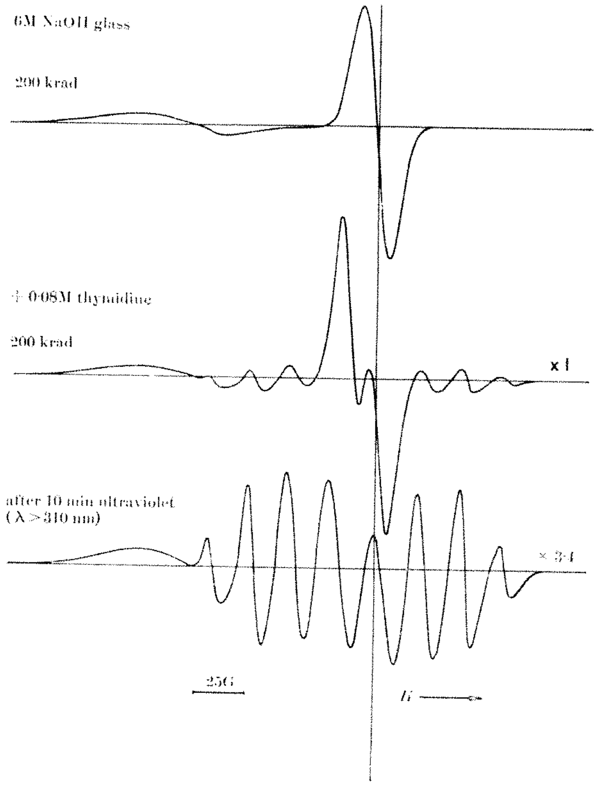

Fig. 1. ESR of 6 M NaOH glasses at 77 K. The samples were γ-irradiated at 77 K to a dose of 200 krad. The upper spectrum is of irradiated 6 M NaOH, the centre spectrums is with 0·08 M thymidine, and the lower spectrum shows the effect of 10 min ultraviolet bleaching (above 310 nm) on the latter sample. The vertical axis shows the resonance position of diphenyl picryl hydrazyl (DPPH). The relative amplifier gains are shown.

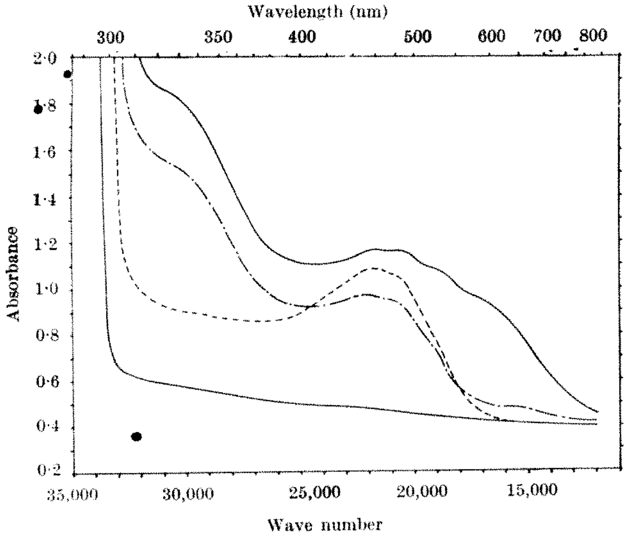

Fig. 2. Optical absorption spectra of 0·08 M thymidine in a 6 M NaOH glass at about 90 K. Upper solid line, after 400 krad γ-irradiation at about 90 K; broken line, same sample after 20 min white light bleaching; dashed line, same sample after 20 min ultraviolet bleaching (above 310 nm); lower solid line, unirradiated base line.

It has previously been postulated that the thymine radical ($TH^{\bullet}$) is formed in γ-irradiated thymidine, thymidylic acid and DNA, not by the direct addition of a hydrogen atom to the thymine ring, but by protonation of the thymine anion (T^-) (refs. 7, 8). Although there is good evidence to support this postulate, part of the argument is based on the assignment of the ESR doublet to T^-. Firm identification of this species confirms the previously published reaction mechanism[8]. Thymidine and cystamine compete for electrons in irradiated frozen solutions at 77 K (ref. 8), and in suitable conditions e_t^-, T^- and $(R{-}S{-}S{-}R)^-$ are all present. On warming, electrons appear to transfer to cystamine. The optical spectra can be used to follow these changes (these reactions will be described elsewhere).

We have shown here that the broad singlet at $g = 2{\cdot}01$ observed in the ESR spectrum of cystamine arises from a disulphide anion. Similar ESR spectra have been observed in oxidized glutathione and cystine-containing proteins irradiated at 77 K (refs. 10, 18). These spectra, which are reduced in intensity in the presence of electron scavengers, arise from disulphide anions. It has been clearly demonstrated that their reactions at room temperature leads to the formation of the radical $R{-}CH_2{-}S^{\bullet}$ (refs. 18–20). Our identification of the disulphide anion fully confirms the earlier postulate that the sulphur radicals observed in irradiated proteins are formed by the reaction of electrons produced by radiation.

We thank Professor A. Charlesby for his support and encouragement, Dr E. M. Fielden and Mr G. Stevens for making available their unpublished data and Mr Stevens for discussions. This work was partly supported by grants to the Chester Beatty Research Institute, Institute of Cancer Research, from the Medical Research Council, the British Empire Cancer Campaign for Research and the National Cancer Institute, US Public Health Service.

Correlation of Bradykinin Structure with ability to increase Vascular Permeability

OF the chemical substances that possibly mediate the inflammatory response[1,2], bradykinin (H–L-Arg–L-Pro–L-Pro–Gly–L-Phe–L-Ser–L-Pro–L-Phe–L-Arg–OH) warrants special study because four of its pharmacological activities—the capacity to increase vascular permeability and to initiate vasodilation, pain and the emigration of leucocytes—are all encountered in acute inflammation[3]. We have sought a correlation of the structure of bradykinin with its ability to increase vascular permeability. The effect on activity was investigated when each of the nine amino-acids in the peptide chain was replaced in turn with L-alanine.

Reference bradykinin and its 1-alanine analogue (H–L-Ala–L-Pro–L-Pro–Gly–L-Phe–L-Ser–L-Pro–L-Phe–L-Arg–OH) were synthesized[4] by the Merrifield solid phase method[5]; samples of synthetic bradykinin and other analogues[6] were supplied by Dr E. Schröder, Hauptlaboratorium der Schering AG, Berlin.

The two synthetic bradykinin samples and the analogues were assayed against histamine and natural bradykinin (Sandoz) by intradermal injection in the dorsal skin of depilated albino guinea-pigs and closely shaven rabbits which had previously received intravenous Evans blue[7]. The dye becomes bound to plasma albumin, and local exudation of the dye–albumin complex registers increased vascular permeability which was estimated from the diameter and intensity of the blue lesions, 30 min after intradermal injection of the test factors[7,8]. Each point on the dose-response graphs (Fig. 1) represents the mean of eight lesions in four guinea-pigs or two rabbits for each test concentration of a permeability factor[7]. Relative permeability factor activity was estimated from reasonably parallel dose-response curves at lesion diameters of 7–8 mm. Fig. 1 illustrates the dose-response relationship in the guinea-pig for the most active alanine analogue, [Ala^3]-bradykinin, compared with those of the two standards.

Table 1 records the permeability factor potency of the nine alanine analogues, relative to natural bradykinin (which is assigned an arbitrary value of one). Bradykinin A synthesized by the Merrifield method had a relative potency of 0·5–0·8 which is similar to that (0·6–0·8) of bradykinin B synthesized by Dr Schröder according to classical methods. In both the rabbit and guinea-pig the

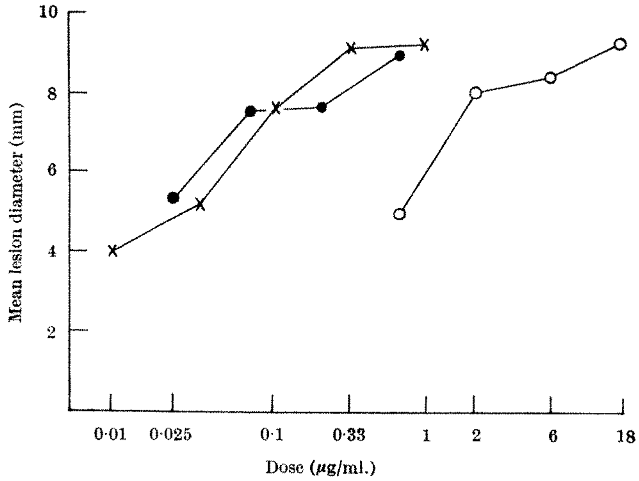

Fig. 1. Dose-response lines for permeability factor in the guinea-pig. ●, Bradykinin; ○, histamine; ×, [Ala^{3}]-bradykinin.

order of potencies is [Ala^{3}]-bradykinin > [Ala^{6}]-bradykinin > [Ala^{7}]-bradykinin; the remaining analogues have no significant activity. This order of potency resembles that from assays using the rat uterus, guinea-pig ileum and rabbit blood pressure[9], and suggests a similarity in mechanism of action or site of reaction in the two systems.

Table 1. RELATIVE PERMEABILITY FACTOR POTENCY OF BRADYKININ AND ANALOGUES IN THE GUINEA-PIG AND RABBIT

Permeability factor	Residue substituted	Guinea-pig	Rabbit
[Ala^{1}]-bradykinin	Arg	0·0025	0·002
[Ala^{2}]-bradykinin	Pro	0·002	0·0125
[Ala^{3}]-bradykinin	Pro	1	1
[Ala^{4}]-bradykinin	Gly	0·002	0·002
[Ala^{5}]-bradykinin	Phe	0·002	0·002
[Ala^{6}]-bradykinin	Ser	0·25	0·125
[Ala^{7}]-bradykinin	Pro	0·025	0·008
[Ala^{8}]-bradykinin	Phe	0·002	0·002
[Ala^{9}]-bradykinin	Arg	0·0025	0·002
Histamine	—	0·04	0·062

We conclude that there are three sites on the bradykinin molecule—the centre and the two ends—which contribute predominantly to its biological activity. In the centre, the substitution of a methyl group for hydrogen in the 4-alanine analogue, or a hydrogen for a phenyl group in the adjacent phenylalanyl residue, leaves no significant activity. This can be attributed in each case to a steric effect. Neither the size nor the polar nature of the hydroxyl group of the seryl residue in the 6-position seems to contribute significantly to the biological activity of the molecule, for the replacement of hydroxyl with hydrogen results only in a relatively small change of activity.

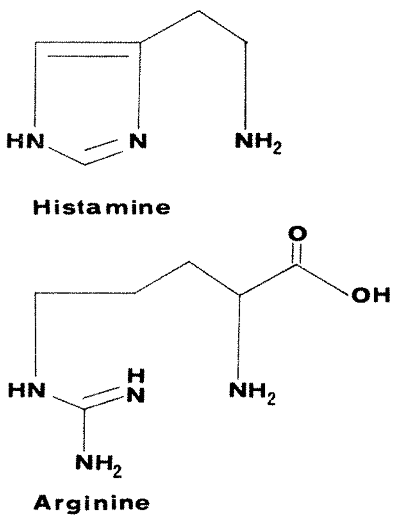

Fig. 2. Structural similarity between histamine and arginine.

The two ends of the molecule have in common a very basic arginyl residue, which exerts a dominant influence on activity. Structurally, arginine resembles histamine (Fig. 2) and this similarity may account, in part, for the similar biological activities of histamine and bradykinin. The replacement of the phenylalanyl and prolyl residues with alanyl in the 8 and 2-analogues, respectively, must bring about a substantial change in molecular conformation, probably a displacement of the neighbouring arginyl residues.

Thus bradykinin has an active site similar to histamine at each end of the peptide chain and at the centre, a site important for its active conformation; this is compatible with the suggestion[10] that bradykinin exists in a cyclic form.

Biosynthesis of Insulin in Anglerfish Islets

It is now well established that insulin is synthesized according to the proinsulin route[1-4]. Our studies are concerned with the mechanisms of biosynthesis in anglerfish islets. The anglerfish insulin was isolated chromatographically on CM-cellulose as previously described[5,6]; a typical chromatogram is presented in Fig. 1. The main components of the first two peaks were found to be two peptides which have amino-acid compositions similar to that of hog glucagon.

Amino-acid analyses of the material recovered from effluent of peak 3 indicated that it had no apparent relationship with insulin. Insulin (peak 4) was eluted at 15–16 mΩ^{-1} and was eventually recovered in the hydrochloride form[5,6]. The specific activity of the anglerfish insulin was found to be 25 to 26 IU/mg according to the mouse convulsion assay. Amino-acid analyses after acid hydrolysis revealed a molar composition in excellent agreement with the theoretically expected values for anglerfish insulin[7].

Peak 5 was eluted after insulin; it was always very small and at times invisible. It could, however, be located easily in pulse labelled experiments because of the significant radioactivity.

The results of several incorporation experiments with fresh anglerfish islets incubated with L-^{3}H-proline can be summarized as follows: (*a*) The specific radioactivity of the isolated insulin (cpm/mg) was found to increase with the time of incubation. (*b*) Only after incubation of the islets for at least 40 min did radioactivity begin to appear in insulin. (*c*) L-^{3}H-proline was found to be incorporated into the material of peak 5. Incorporation of ^{3}H-proline into this protein preceded that into insulin and the specific activity of this material was several-fold higher than that of insulin (Fig. 1, I). (*d*) Further, it was found that arrest of protein synthesis by sparsomycin[8] and continuation of incubation after the addition of the antibiotic resulted in increased radioactivity in the insulin peak and a comparable decrease of radioactivity in the area of peak 5 (Fig. 1, II). The continuous increase of the specific radioactivity of insulin in the absence of protein synthesis indicates that the conversion of precursor(s) to insulin is not dependent on protein synthesis. Further, the decline in the radioactivity of peak 5 correlates with the increased radioactivity in the insulin peak, which strongly suggests that the material of peak 5 may be a precursor of insulin. Clearly, although the synthesis of this precursor has been arrested by the inhibitor, its conversion to insulin has not.

The material from peak 5 was recovered in the hydrochloride form and amino-acid analyses (Table 1) gave an amino-acid composition different from that of insulin but comprising all the amino-acids present in insulin.

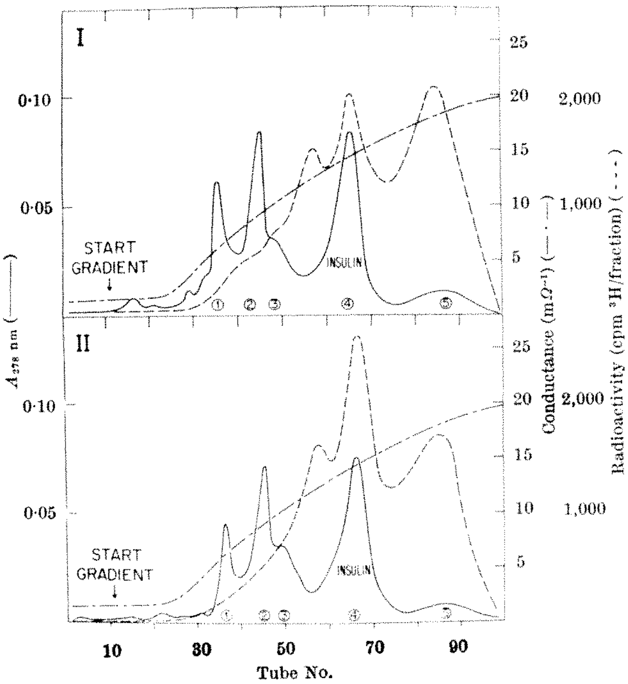

Fig. 1. I, Column chromatography of material obtained from 16 anglerfish islets incubated for 75 min in the presence of 0·5 mCi of ^{3}H-proline. The minced islets were incubated in 5 ml. of incubation medium at *p*H 7·4 under 95 per cent O_2/5 per cent CO_2 in the presence of L-^{3}H-proline in a Dubnoff metabolic shaker at 20° C. The incubation medium was Hanks salt solution containing 350 mg/100 ml. of glucose and 2 mg/100 ml. of each of the naturally occurring amino-acids, excluding proline. After 75 min of incubation, trichloroacetic acid (TCA) was added to a final concentration of 10 per cent and insulin was isolated as follows: (*a*) homogenization of islets in 10 per cent TCA; (*b*) extraction of the precipitate with HCl-ethanol; (*c*) evaporation in a rotary evaporator; (*d*) extraction of lipids with methylene chloride; (*e*) precipitation with TCA and extraction of the precipitate with acetic acid/NaCl; (*f*) precipitation with picric acid; (*g*) chromatography on a CM-cellulose column. Steps (*a*)–(*e*) have been described by Humble and Crestfield[7]. Steps (*f*) and (*g*) have been described previously[5,6]. During chromatography the effluent was monitored by a Gilford recording spectrophotometer and a conductivity meter. The effluent was collected in 2 ml. fractions with the aid of a fraction collector. 0·5 ml. of a fraction was pipetted into 14·5 ml. of Bray's scintillation liquid and the radioactivity was counted. II, Column chromatography of material obtained from sixteen anglerfish islets incubated for 75 min in the presence of 0·5 mCi of ^{3}H-proline. Then 0·1 mg of sparsomycin was added to the islet suspension and the incubation was continued for another 75 min. The incubation media and techniques are as described for I.

* Number of amino-acid residues per molecule according to analysis by the method of Spackman *et al.*[9] in a Beckman-Spinco analyser (model 120C) equipped with a digital readout system.

† Minimum possible number of amino-acid residues.

The N-terminal amino-acid was determined by the dansyl technique[10] and found to be valine, which is also the N-terminal residue of the B-chain of anglerfish insulin. This protein was incubated with 10 µg of trypsin in 0·05 M Tris buffer (*p*H 7·5) at 37° C for 2 h, and cold anglerfish insulin was added. On chromatographic separation most of the radioactivity was eluted with the insulin. We conclude that this protein represents the anglerfish proinsulin. According to the mouse convulsion assay method, the insulin-like activity of proinsulin was less than 2·5 IU/mg.

Effect of L-Asparaginase from *Aspergillus terreus* on Ascites Sarcoma in the Rat

IT is well known that L-asparaginase (L-asparagine amidohydrolase, EC 3.5.1.1) is the antitumour agent in guinea-pig serum[1]. The same antitumour activity has been demonstrated for the L-asparaginase from *Escherichia coli*[2] and recently for that from *Erwinia carotovora*[3]. L-Asparaginase preparations from other bacteria[2,4] or yeast[5] have no inhibitory action. After screening a number of microorganisms, a strain of *Aspergillus terreus* which produces an L-asparaginase active against Walker 256 ascites carcinosarcoma[6] has now been isolated.

The organism was grown for 48 h at 24° C in submerged culture on nutrient broth (*p*H 7) containing 5 per cent peptone, 1 per cent beef extract, 5 per cent mannitol in distilled water. The cells were harvested by filtration, washed with distilled water and disrupted with the 'X' press (Biox, Nacka, Sweden). The enzyme was extracted with 0·02 M phosphate buffer (*p*H 8), according to the procedure described by Roberts *et al.*[4] and partially purified through a column of 'Sephadex *G*-50' gel. This extract, tested according to the method of Roberts *et al.*[4], exhibited an activity of 66 I.U./g mycelial dry weight (0·6 I.U. per mg protein) in 0·1 M Tris-phosphate buffer (*p*H 7) at 37° C. The *A. terreus* asparaginase has optimum activity at *p*H 6–8 (Fig. 1).

The antitumour activity of this enzyme preparation was compared with that of guinea-pig serum on a Walker 256 carcinosarcoma growing in ascitic form in the peritoneal cavity of the rat. Male Wistar rats, weighing approximately 80 g, were divided into three groups each consisting of eighteen animals. All animals were inoculated intraperitoneally with about 5×10^5 tumour cells. Rats of one group then immediately received 2·5 ml. of sterile 0·154 M NaCl, intraperitoneally. Animals of the other two groups received 2·5 ml. of either guinea-pig serum or *A. terreus* L-asparaginase preparation dissolved in saline, both containing 4·0 I.U. of enzyme. The same treatments were repeated every 24 h for 8 days. All treatments were tolerated by the animals.

Table 1. EFFECT OF GUINEA-PIG SERUM AND OF L-ASPARAGINASE FROM *Aspergillus terreus* ON WALKER 256 ASCITES CARCINOSARCOMA IN THE RAT

Treatment	No. of rats	Healthy survivors after 60 days	Mortality in less than 60 days from Ascitic tumour	Combined ascitic and solid tumour	Solid tumour	Survival time (days)
Saline	18	0	2	16	0	21·7 ± 1·2
Guinea-pig serum	18	5	10	3	0	41·1 ± 1·0*
A. terreus asparaginase	18	4	1	2	11	41·0 ± 2·7*

* $P < 0·01$.

The results (Table 1) show that the asparaginase produced by *A. terreus* has a carcinostatic effect on Walker 256 ascites carcinosarcoma. As compared with guinea-pig serum, this preparation of *A. terreus* asparaginase has a greater carcinostatic effect on the ascitic tumour and a smaller effect on those solid tumours that frequently develop in the subcutaneous at the inoculation site.

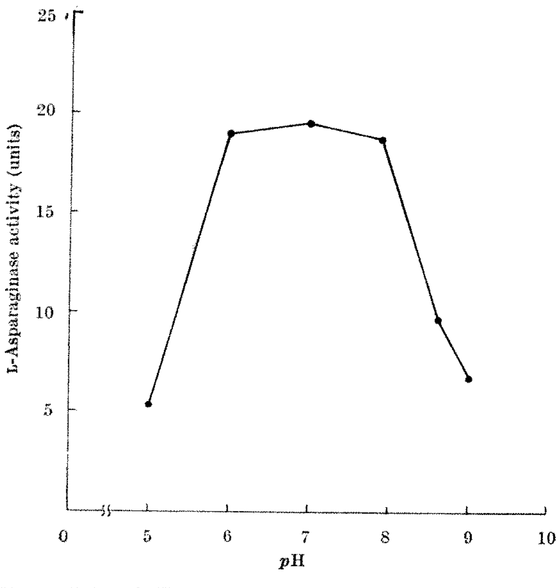

Fig. 1. Effect of *p*H on *A. terreus* L-asparaginase. Assays were carried out in 0·0285 M citric acid–barbital–KH_2PO_4–boric acid buffer, as described by Roberts *et al.*[7]. The *p*H was determined before and after incubation.

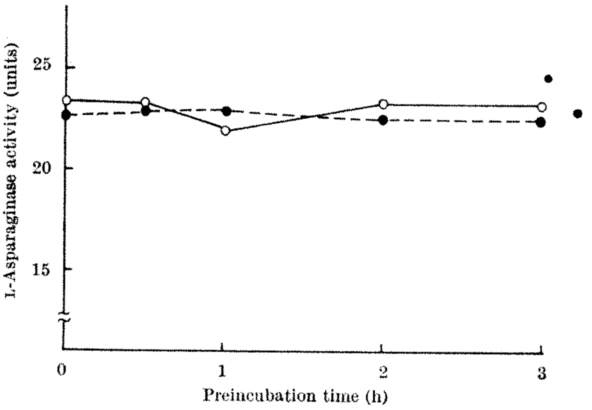

Fig. 2. Stability of *A. terreus* L-asparaginase. ●– – –●, 0·05 M phosphate buffer (*p*H 6·8); ○——○, rat ascitic fluid.

The *A. terreus* asparaginase was tested after preincubation at 37° C either in 0·05 M phosphate buffer (*p*H 6·8, the *p*H of the peritoneal fluid) or in rat ascitic fluid (Fig. 2). At intervals, aliquots of the incubation mixtures were assayed for L-asparaginase activity according to the method of Roberts *et al.*[7] with few modifications (the incubation mixtures contained 0·1 M Tris-HCl buffer, *p*H 7·0, instead of 0·05 M Tris-HCl buffer, *p*H 8·5). Because the *A. terreus* asparaginase is not inactivated either at the *p*H of the peritoneal fluid or by the ascitic fluid, the weak activity on solid tumours may be correlated with the low diffusibility of this enzyme preparation from the peritoneal cavity into the blood stream.

Although it seems improbable, we cannot exclude the possibility that the antitumour activity is to be attributed to other proteins present in *A. terreus* extracts, because of the low degree of purity of the product.

We thank Professor A. Ballio, Istituto Chimico, University of Naples, for his advice and encouragement.

Immunosuppression by L-Asparaginase

L-ASPARAGINASE, an enzyme which occurs in the serum of certain rodents and is produced by various micro-organisms, catalyses the hydrolysis of asparagine to L-aspartic acid and ammonia. It has been found useful in the treatment of acute lymphoblastic leukaemia and in occasional cases of other types of neoplasm in man[1].

It has been shown recently that the phytohaemagglutinin-induced transformation of normal human lymphocytes is inhibited by asparaginase *in vitro*[2] and *in vivo*[3]. I have studied the effects of asparaginase on antibody producing cells. Similar investigations were made independently during the course of this work by Dr L. G. Lajtha and Professor P. Alexander, and their findings accord with some of those described here.

Male Balb/C mice, weighing 15–20 g, were injected intraperitoneally with 0·2 ml. of a 10 per cent suspension in saline of formalized sheep red cells (Burroughs Wellcome). Spleens were removed 4 days later (except as described here) and the numbers of cells producing IgM haemolysin counted by Jerne's method[4]. The results are here expressed as fractions of the geometric mean control value (which varied in different experiments from 40,000 to 140,000 antibody-forming cells per spleen on day 4).

The initial experiments were carried out with Bayer asparaginase, which is prepared from *Escherichia coli*. It was at first assumed that asparaginase would be most effective 2 days after the antigen injection, when immunocytes would be proliferating most rapidly. Even doses of 5,000 IU per mouse (or about 250,000 IU/kg) given intravenously at that time had little effect, however, reducing the number of splenic haemolysin-producing cells to 0·7 of the control value. The effect of varying the time of injection of enzyme relative to that of the antigen was therefore investigated.

Mice were given single intravenous injections of 1,000 IU Bayer asparaginase at various times before or after sheep red cells. There was a clear-cut time dependence in the immunosuppressive effect, the enzyme being maximally effective when given during the period from 24 h before to 4 h after the antigen (Fig. 1).

Mice were given 1,000 IU asparaginase 24 h before sheep red cells and spleens examined 2, 4, 6, 9 and 12 days later. Depression of the antibody response was temporary—the number of antibody-forming cells approached control values by day 6 (Fig. 2). At an early stage of the investigation, Professor P. Alexander pointed out that the doses of enzyme required for immunosuppression were relatively enormous, and suggested two explanations for this. First, asparaginase preparations of bacterial origin have lower glutaminase activity, and immunosuppression could have arisen from this and not the asparaginase. Second, the enzyme has a half-life *in vivo* of only a few hours[1,5]. If cell susceptibility depends on the duration of exposure to the agent and only single injections are given, inordinately high doses might be needed to keep the *in vivo* concentration high enough over a long enough fraction of the cell cycle. These possibilities were tested by comparing the effects of asparaginase preparations with differing glutaminase activities and differing half-lives.

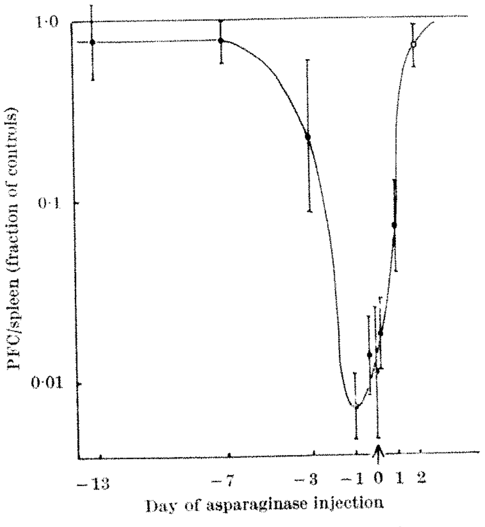

Fig. 1. Time dependence of immunosuppression by asparaginase. Sheep red cells given intraperitoneally on day 0. Asparaginase, 1,000 IU, given intravenously at various times before, on or after day 0 (5,000 IU given on day +2). Spleen plaque-forming cells (PFC) counted on day 4. (Eight mice per point.)

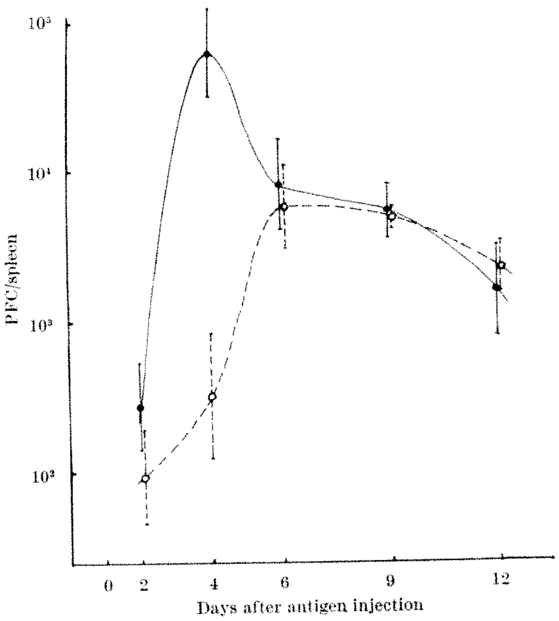

Fig. 2. Duration of immunosuppression by asparaginase. Sheep red cells given on day 0. ●——●, 0·5 ml. saline given intravenously on day −1; ○– –○, 1,000 IU asparaginase in 0·5 ml. saline given intravenously on day −1. (Five mice per point.)

The three materials used were the *E. coli* enzymes produced by Bayer and Squibb and the *Erwinia carotovara* enzyme produced by the Microbiological Research Establishment at Porton. Various doses of these in 0·5 ml. saline were given intravenously to mice 24 h before sheep red cells. The resulting degrees of immunosuppression are shown in Fig. 3.

All three preparations gave dose-response curves fitting the equation for a hyperbolic curve[6]: $F = [D_0/D]^{-\gamma}$, where F is the surviving cell fraction, D the dose, D_0, the threshold dose and $-\gamma$ the slope of the curve. The value of γ is not much different from unity for any of the preparations. The value of D_0 is about 15 IU for the Squibb, 25 IU for the Bayer and 200 IU for the Porton material. The Squibb enzyme is therefore about thirteen times and the Bayer eight times as potent as the Porton enzyme. The glutaminase activities of the three preparations are in the order Porton > Squibb > Bayer; the *in vivo* half-lives are in the order Squibb > Bayer > Porton (personal communication from P. Alexander). It is therefore unlikely that immunosuppression in this system is to be attributed to glutaminase, but the results are consistent with immunosuppressive effectiveness being a function of the half-life—the enzyme that persists longest in the circulation is the most effective. It is relevant that asparaginase from guinea-pig serum—which has a half-life in the mouse of 19 h—is very active against mouse lymphoma, whereas yeast asparaginase, with a half-life of less than 30 min, is inactive[7].

Although cell survival here seems to be related to the duration of exposure to enzyme, it is unlikely that asparaginase is a phase-specific agent in the sense of Bruce *et al.*[8], that is, one that destroys or sterilizes cells exposed to it above a threshold concentration while in a particular phase of the cell cycle. For such an agent, a plot of cell survival against dose of agent, both on linear scales, should in theory give a line which is straight[9], or very nearly straight[10], depending on what assumptions are made in the calculations. The curves in Fig. 2 would, however, not be even remotely linear when plotted in this way and therefore do not support the hypothesis that asparagine acts as a phase-specific agent, at least in the simple sense outlined here.

Further, the effectiveness of phase-specific or cycle-specific agents is characteristically greater for rapidly proliferating cells than for resting cells[11]. The effectiveness of asparaginase is, however, greatest if given just before the antigen, when there is relatively little cell proliferation, and it is practically ineffective if given 2 days after the antigen, when cell multiplication is most marked. This again throws doubt on the phase specificity of asparaginase, although it does not disprove it, for special factors may operate in this system.

If the relative ineffectiveness of the *Erwinia* enzyme in the experiments was the result of inappropriate timing of the injection in relation to its unduly short half-life—that is, if the critical time for exposure of mice to the enzyme began a few hours before injection of antigen and its *in vivo* concentration when injected 24 h previously had fallen too far by that time—then administration nearer the critical time should be more effective. Mice were accordingly given 1,000 IU of one or other enzyme preparation intravenously 15 h, 3 h or 1 min before an intraperitoneal injection of sheep red cells. Fig. 4 shows that the degree of immunosuppression hardly varied, so that this explanation for the lack of potency of the *Erwinia* enzyme does not hold.

The time dependence curve (Fig. 2) suggests that asparaginase affects the cells mediating the immune response at about the time of exposure to antigen and that effectiveness is lost once the cells begin to multiply rapidly, which may be relevant to the action of asparaginase in acute leukaemia. There are several possible explanations for this anomalous sensitivity: (*a*) rapidly proliferating lymphoid cells may normally synthesize asparagine, (*b*) production of asparagine synthetase when induced by lack of exogenous asparagine may be much more rapid in proliferating than in resting cells, (*c*) lymphocytes may be able to obtain exogenous asparagine from feeder cells in the changed milieu of an antigenically stimulated spleen, (*d*) asparaginase may act on macrophages and not on lymphocytes during ingestion and processing of antigen (although one might expect, in this case, that the preparation most rapidly removed from the circulation, that is, with the shortest half-life, would be the most active), (*e*) asparaginase might act on lymphocytes or a subpopulation of lymphocytes involved in the initial stages of antigen recognition, so that administration subsequent to this step would be ineffective.

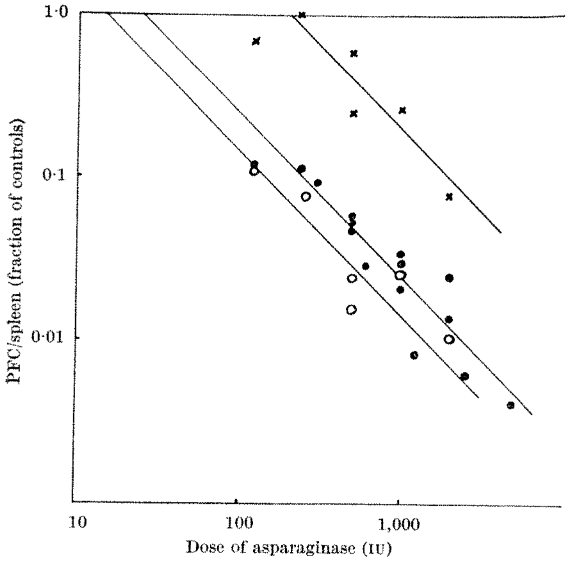

Fig. 3. Dose-response curves for three asparaginase preparations, given in various doses intravenously 24 h before sheep red cells. Spleen plaque-forming cells (PFC) counted on day +4. ×, *Erwinia carotovara* asparaginase; ●, *E. coli* asparaginase (Bayer); ○, *E. coli* asparaginase (Squibb). (Six mice per point.)

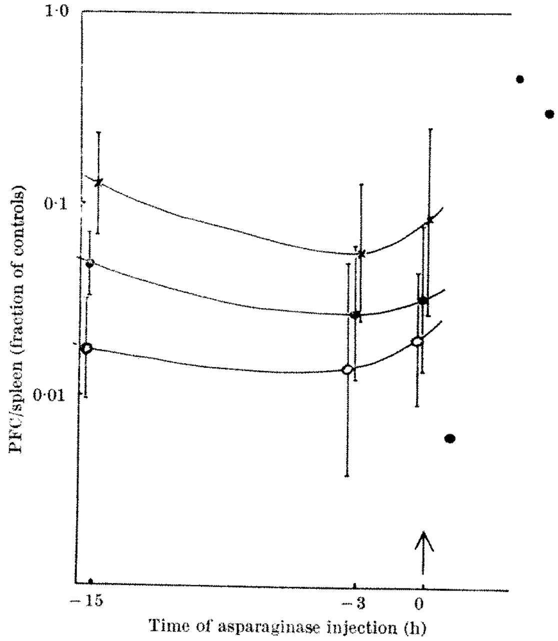

Fig. 4. Time dependence for different asparaginase preparations. Sheep red cells given intraperitoneally at time 0. Asparaginase, 1,000 IU, given intravenously at −15 h, −3 h or −1 min. Spleen plaque-forming cells (PFC) counted on day 4. ×, *Erwinia carotovara* asparaginase; ●, *E. coli* asparaginase (Bayer); ○, *E. coli* asparaginase (Squibb). (Six mice per point.)

Histological studies show that injection of 1,000 IU asparaginase leads to necrosis of lymphoid cells in the thymic cortex and the germinal centres of the mouse spleen and lymph nodes. These changes are greatest 4–8 h after the injection. Atrophy of the thymic cortex follows at 24–48 h.

I thank Professor P. Alexander, Professor R. M. Hardisty and Dr H. E. M. Kay for supplies of asparaginase and Miss L. Stephenson for assistance. This work was supported by the British Empire Cancer Campaign for Research, the Leukaemia Research Fund and the Nuffield Foundation.

Maths Teaching

The liveliest job a graduate can tackle

That means an exciting future for a maths graduate like you. Developing the latest teaching techniques. Showing bright young minds how to solve the problems of an increasingly computer-minded, technological world. Enjoying the satisfaction of a career you can really make progress in; one that can fulfil your hopes and ambitions perhaps better than any other.

Certainly the need for mathematicians, scientists, engineers and technicians will be tremendous. People like you to teach them will always be in demand. And mathematics teaching need never be a frustrating, dull or dead-end job.

The scope is immense. Over 40% of maths and science graduates who started teaching seven years ago are already heads of departments. One in five graduates over 40 is a head teacher, while for others teaching leads to a further career in educational research or administration.

Jobs for mathematics teachers are available in almost every part of the country. And there are long holidays.

Pay and prospects. Starting salaries are competitive with industry, ranging for graduates from £965 to £1,170. Looking forward, as head of a large department you could earn over £2,600; a deputy headship could take you above the £3,000 mark. Promotion, like responsibility, is seldom long in coming when you're a mathematics teacher. There are also many good posts in colleges of education and as an inspector, as well as in administration. Want to find out more about teaching? Send for our free booklet 'Careers in Education for Graduates'. Available from: The Department of Education and Science (Dept. N.1, Room 107), Curzon Street, London, W1Y 8AA.

Are you already in employment? Before it's too late, measure what you're doing now against teaching. Is it as interesting as you expected? Are the prospects as good? Are you in charge of your own daily activities in the way a teacher is? You can still come into teaching—you'll be *very* welcome.

Looking forward?

TEACH MATHS

There are eleven good reason why over half of the Infrared Spectrophotometers in the world are from Perkin-Elme

They are the Models 700, 137, 157, 257, 457, 21, 221, 421, 521, 621, 325. From this range of eleven instruments you can easily choose the one that is exactly right for you. The reliable low-cost 700 for teaching and routine work, the fast-scan 157 for high sample throughput and the 325 for its unequalled performance; these are some of the reasons for the universal use of Perkin-Elmer spectrophotometers. Together with a comprehensive range of accessories, from a new concept in liquid cells to such specialised items as 1 and 10 metre gas cells, wire-grid polarisers and the ultra micro KBr disc equipment.

Immunoglobulin Determinants on the Surface of Mouse Lymphoid Cells

THERE is increasing evidence that lymphocytes have antigen-specific receptors on their surface[1-3] and it seems reasonable to suppose that the receptors are immunoglobulins (Ig)[1]. The existence of Ig on the surface of lymphocytes has also been inferred from the transforming effect of anti-Ig sera[4] and the opsonic adherence to macrophages of lymphocytes treated with anti-Ig[5]. We report here the demonstration of Ig determinants on the surface of living mouse lymphocytes by the use of immunofluorescence and immunoautoradiography.

Fluorescein-labelled anti-Ig has commonly been used to demonstrate Ig within the cytoplasm of lymphoid cells[6]. In all of these studies the tissues have been frozen and/or fixed, and the fluorescence has been largely confined to the cytoplasm; the majority of cells stained have been plasma cells. Surface staining was first encountered by Möller[7] as an unavoidable background in his study of histocompatibility antigens by indirect immunofluorescence on living lymphocytes. More recently, surface fluorescence has been observed in cultured Burkitt lymphoma cells[8]. We have treated normal living mouse lymphoid cells with either fluorescein-labelled or ^{125}I-labelled rabbit anti-mouse immunoglobulin (fl-anti-M Ig or ^{125}I-anti-M Ig) and report here experiments designed to prove that the staining observed does indicate the presence of Ig on the cell surface and that only a certain proportion of the lymphoid cells become stained—a proportion which is characteristic of the tissue examined.

The anti-M Ig was prepared by immunizing rabbits with an Ig fraction from normal mouse serum for fl-anti-M Ig, and with myeloma protein 5563 (ref. 9) for ^{125}I-anti-M Ig, both in Freund's complete adjuvant. The rabbit antisera were fractionated on DEAE-cellulose and that fraction which was not adsorbed to the resin in 0·02 M phosphate buffer at *p*H 7·5 was used. It was conjugated with fluorescein isothiocyanate (FITC) by a modification of the dialysis method of Clark and Shepard[10]. The Ig fraction was adjusted to 10 mg/ml. and *p*H 9·5 in buffered saline (0·05 M phosphate–0·075 M NaCl) and was dialysed for 24 h at 4° C against 10 volumes of FITC solution at 0·125 mg/ml. in the same buffer. The conjugate was dialysed against phosphate buffered saline (PBS) at *p*H 7·3 until fluorescein was no longer detectable in the dialysate. The conjugate was absorbed with acetone dried mouse liver powder just before use. Iodination was carried out by the method of Hunter and Greenwood[11] as modified by Klinman and Taylor[12]. Details of the specificities of these labelled antisera will be published elsewhere (submitted to *Immunology*).

Cell suspensions were prepared as previously described by Raff[13] for immunofluorescence and by Klinman and Taylor[12] for autoradiography. The only significant difference between the two methods concerns the use of ammonium chloride to lyse the red cells for fluorescence studies. Immunofluorescent labelling of the cells was carried out by the method of Möller[7]. Equal volumes (0·025 ml.) of cells (20×10^6/ml.) in veronal buffered saline (VBS) with 5–10 per cent foetal calf serum (FCS) and fl-anti-M Ig (10 mg/ml.) were mixed and incubated for 15 min at room temperature. The cells were washed twice and resuspended in VBS with 5–10 per cent FCS and examined under a coverslip with ultraviolet light. 100–300 cells were counted and the percentage of cells showing surface fluorescence was determined.

For autoradiographic studies the cells were stained similarly, except that the ^{125}I-anti-M Ig was used at a much lower concentration (approximately 1 μg/ml.). The stained cells were diluted to 1×10^6/ml. and 0·1 ml. was mixed with 0·3 ml. of 0·6 per cent agarose in VBS and spread on an agarose-subbed slide. The slides were fixed for 10 min in 0·25 per cent glutaraldehyde in PBS, washed for 10 min in 0·5 per cent glycine (adjusted to *p*H 9) to inactivate the glutaraldehyde, and finally washed for 10 min in distilled water and dried in a current of warm air. The slides were then dipped in 1 : 3 dilution of Ilford *G*-5 emulsion and exposed for 1–7 days. The autoradiographs were developed in Ilford *D 19b* and stained with methyl green. 100–500 cells were scored and any cell judged to have more than background label was counted as bearing Ig. By 7 days' exposure, the difference between labelled and unlabelled cells became very obvious.

Various lymphoid tissues of normal adult CBA and Balb/c mice were examined and the results are shown in Table 1. The two methods gave similar results and the number of lymphocytes bearing Ig on their surface was approximately 40 per cent in spleen, 20 per cent in lymph node, and 15 per cent in thoracic duct and bone marrow. Titrations were performed with both methods and showed that the percentage of stained cells increased with increasing concentration of anti-M Ig up to a plateau beyond which no more cells could be labelled. The plateau was reached at 0·05 μg/ml. of ^{125}I-anti-M Ig and at 500 μg/ml. of fl-anti-M Ig. The fact that the two methods stained approximately the same percentage of cells in any one tissue, despite the very great difference in sensitivity, suggests that there are at least two distinct populations of lymphocytes, one bearing Ig on their surface and one having very much less or no surface Ig. With immunofluorescence the staining had a striking distribution, most of the labelled cells showing a clearly defined fluorescent "cap" occupying approximately one-fifth to one-third of the cell surface and usually overlying a pseudopod-like structure.

Table 1. PERCENTAGE OF IMMUNOGLOBULIN-BEARING CELLS IN VARIOUS TISSUES OF NORMAL MICE

* Experiments using Balb/c mice. In all other experiments CBA mice were used.

Control experiments were done to establish that the staining of cells with the anti-M Ig was the result of the presence of Ig on the cell surface. Ig fractions of normal rabbit serum were prepared and labelled with fluorescein and ^{125}I as before and did not stain normal mouse lymphoid cells. With both fluorescence and radiolabelling techniques, the staining could be strikingly inhibited by pretreating the cells with unlabelled rabbit anti-M Ig.

The morphology of the labelled cells has not been studied, but smears of cell suspensions of lymph nodes, spleen, thoracic duct and thymus stained with Wright's stain and methyl green pyronine all show that the great majority of the nucleated cells are lymphocytes[13]. Thus most labelled and unlabelled cells in these tissues must clearly have been lymphocytes. Although it might be expected that macrophages with cytophilic antibody on their surface would become labelled by these methods, they could only account for a small percentage of the labelled cells in most of the tissues examined.

The origin of the immunoglobulin on the surface of lymphocytes is uncertain. The three obvious possibilities are that it is adsorbed from the serum, transmitted from outside the cell to the cell surface by an active process, or it could be a product of the cell which bears it. The first hypothesis seems unlikely, because thymus lymphocytes failed to stain for surface Ig after incubation in normal mouse serum for 30 min, followed by washing, although this does not exclude the possibility of *in vivo* adsorption. Preliminary experiments with class-specific anti-M Ig suggest that the Ig on any one cell belongs to a single class. This result is most easily reconciled with the third hypothesis. The question of whether the surface Ig molecules function as antigen-specific receptors remains to be answered.

We thank Mr R. Lucken, Mr A. Savill and Miss J. Cressey for their technical assistance, and Dr B. A. Askonas for the anti-M Ig. This work was supported in part by the US National Multiple Sclerosis Society.

Gas Chromatographic Determination of N-Alkyl Nitrosamines

The carcinogenicity, at very low concentrations, of many N-nitrosamines is well established[1,2]. There is a need for improved methods of specific sensitive and quantitative determination of these compounds in samples of interest. Polarographic methods[3-6] are sensitive to rather less than one part per million but they lack specificity. Thin layer chromatography[7-9] offers a measure of discrimination between N-nitrosamines, but the methods so far developed are not entirely satisfactory. A specific and sensitive gas chromatographic method for N-alkylnitrosamines is described below.

The study has been limited to simple N-alkylnitrosamines which are volatile in steam; the separation procedure used has been that of Heath and Jarvis[3]. At the 1 p.p.m. level dimethyl and diethylnitrosamines are recovered to 95 per cent and 97 per cent, respectively, when added to corned beef. The gas chromatographic method is directly applicable to aqueous samples. Using microporous polymer beads as a column packing, water is rapidly eluted in a narrow band which does not interfere with the determination of N-alkylnitrosamines. A typical chromatogram is shown in Fig. 1. A lower limit of detection of 1 p.p.m. (corresponding to 10^{-2} μg in a 10 μl. injection on the column) was achieved using standard solutions, but the practical detection limit for sample extracts would depend upon the degree of purification achieved during the extraction stage. With suitable concentration techniques, such as repeated distillation or evaporation of a suitable solvent, amounts of nitrosamine of the order 0·01 p.p.m. should be detectable. The method is capable of direct extension to the analysis of more complex nitrosamines, but an alternative separation procedure, for example, solvent extraction, is necessary for non-volatile nitrosamines.

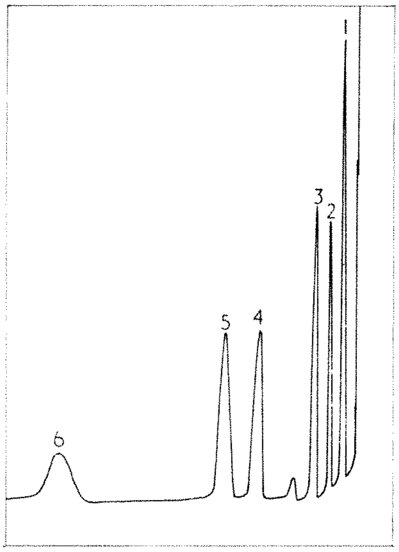

Fig. 1. Chromatogram of mixture of N-nitrosamines. 1, Dimethylnitrosamine; 2, methylethylnitrosamine; 3, diethylnitrosamine; 4, dipropylnitrosamine; 5, methylhydroxyethylnitrosamine; 6, dibutylnitrosamine. The gas chromatograph used was a Varian Aerograph 1200 with a 6 feet × ⅛ inch (outside diameter) stainless steel column packed with Chromsorb 101, at 200° C, with a flame ionization detector. The flow rate was 25 cc/min, chart speed 4 inch/h; 5 μl. samples were taken.

Adaptation to Hamsters of Neurotropic Measles Virus from Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE), a fatal neuropathy of children, has gained prominence recently because of its presumed aetiological association with measles virus[1]. Several successful isolations of the virus from affected brain tissues have been reported[2,3]. Preliminary characterization studies on these isolates have failed to show differences from classical measles virus strains.

This communication describes the adaptation of one of these SSPE measles isolates to brains of baby hamsters. Other strains of measles virus have been adapted to the brains of rodents in the past[4,5], but these strains were non-neural in origin. The virus used in our study was derived from the brain of a documented case of SSPE[6].

The Mantooth strain[2] of SSPE virus was obtained from Dr W. Zeman, Indiana University Medical Center. A pool of stock virus, which had been received as second passage fluids, was prepared in BSC-1 cells[7]; these cells were used throughout the study. To prepare hamster inocula, virus at a high multiplicity of infection was inoculated in bottles of cultured cells. After 24 h at 36° C, cells were scraped from bottles; cellular fluids were centrifuged for 15 min at 1,000*g*; and pellets were resuspended in a tenth of the original volume. Clumps were disrupted by pipetting and cells counted. Approximately 2×10^5 infected cells were injected intracerebrally into each of ten 2-day-old hamsters.

Except for one hamster found dead on the eleventh day of the infection and a second, stunted by the twelfth day, animals were unaffected clinically. The brain of the stunted hamster was removed and processed, and the suspension was inoculated both into a litter of hamsters and into cell cultures. The hamsters did not respond clinically except for one possibly stunted animal, but cytopathic changes characteristic of measles infection were seen in cultures by the sixth day.

The cells were scraped from bottles exhibiting these changes and suspensions of the infected cells were used for inoculation of a litter of hamsters. Each animal was injected intracerebrally with approximately 2×10^4 cells. Because no clinical effects were noted by the seventh day, the brains from two hamsters were removed and prepared for further passage in cell cultures. Syncytia were seen in 72 h and infected cultures haemadsorbed when simian erythrocytes were added. The infected cells were collected and passaged back into hamsters. Thus an alternating hamster-cell culture series was initiated. A total of four pairs of such "to and fro" passages were made with apparent enhancement of virulence occurring in each type of host. Four direct hamster brain to brain passages were then made and a pool of brain grown virus (HBS) was prepared for further study (representing the tenth passage in our laboratory).

Two-day-old hamsters, inoculated intracerebrally with HBS virus, uniformly developed neurological signs in about 3 days. Animals first showed ataxia and weakness, then opisthotonus and death 1 to 2 days after first appearance of illness. The virus titre was found to be $10^{4 \cdot 5}$ LD_{50}/0·02 ml. in baby hamsters. The virus had no clinical effects on neonatal rats and guinea-pigs.

Weanling hamsters (18 days old), similarly injected, responded with a less acute disease but with deaths occurring as early as the fifth day and sporadically thereafter until the twenty-second day after injection. Nineteen of twenty weanlings died. Posterior limb paralysis was noted in several hamsters before death.

Preliminary histological examinations of brains from acutely infected baby animals revealed a severe viral encephalitis with extensive cerebral necrosis. In older hamsters, lesions included glial cell infiltrations, perivascular cuffing, neuronal death and reduced pan-necrosis. Inclusion bodies were not observed in the brains studied so far.

HBS virus grew well in cell cultures, displaying the characteristics of measles effects, including typical nuclear and cytoplasmic inclusion bodies and production of haemagglutinins.

Identification of HBS virus as that of measles was carried out in several ways: (1) specific immunofluorescence was obtained in HBS infected cultures reacted with fluorescein-conjugated γ-globulin (prepared from rabbit antiserum) against classical Edmonston measles virus; (2) rabbit antiserum prepared with the HBS virus neutralized Edmonston virus in cell culture and inhibited Edmonston virus haemagglutination; (3) antiserum against Edmonston virus neutralized HBS virus in cell culture; (4) reference measles antiserum (used by the National Institutes of Health for vaccine strain identification) neutralized HBS virus when tested in cell cultures and inhibited HBS virus haemagglutination.

We are also studying another rodent brain-adapted measles virus variant (HNT) in this laboratory[4,8,9]. The properties of HNT are distinct from those of HBS and include: virulence for hamsters, mice and baby rats; and abortive infection in BSC-1 cells characterized by healing of cytopathic effects, absence of extracellular virus, nondetectable haemagglutinins and failure to haemadsorb. By contrast, HBS virus produces a virulent infection with haemadsorption, complete destruction of BSC-1 cell sheets, high yields of extracellular virus and haemagglutinins. Also, as indicated, clinical signs are not observed in rats injected with HBS virus.

The availability of an SSPE-derived neurotropic measles variant that has been adapted to an experimental host should provide a model for approaching the elucidation of the role of measles virus in SSPE.

This research was supported by a grant from the US National Institute of Neurological Diseases and Stroke.

Similar Polymorphism of Taste Sensitivity to PTC in Mice and Men

INDIVIDUAL differences in taste sensitivity to phenyl thiocarbamate in human populations, first demonstrated in 1931, were soon shown to be due to segregation at a single autosomal locus[1]. Although this phenomenon was initially very interesting, its dependence on a synthetic compound relegated it to a laboratory demonstration of single locus determination of perceptual differences. More recent work concerning the antithyroid activity of PTC and similar compounds in several naturally occurring foodstuffs, however, has prompted renewed interest in this phenomenon[2].

There is some evidence of individual differences in taste sensitivity to PTC in subhuman primates and rodents. Fisher, Ford and Huxley[3] found that the proportion of tasters to non-tasters among the anthropoid apes was similar to that previously found in human populations[1], and they postulated a stable polymorphism which antedated the separation of the anthropoid and hominid stocks. Richter and Clisby[4] later determined individual taste thresholds for PTC in both rat and human populations and found similar distributions. Differences in taste sensitivity to PTC among inbred strains of mice have also been reported[5].

Although these results suggest that individual differences in taste sensitivity to PTC in subhuman species are also hereditary, their mode of inheritance has not been elucidated. We now have evidence that PTC taste sensitivity is determined by a single locus in mice, similar to that in man[6]. Such evidence raises interesting questions about the maintenance of similar polymorphisms in widely divergent species.

In an initial experiment to assess strain differences of mice, six males and six females from each of five inbred strains (A/Ibg, BALB/cIbg, C3H/Ibg, C57Bl/Ibg and DBA/2Ibg) were presented tap water and PTC solutions in a two-choice situation. Thirteen concentrations, ranging from 0·1 to 409·6 mg PTC/l. of tap water, were presented to each subject in ascending order. The concentration of PTC was doubled every second day and cylinder position was reversed daily. A daily preference ratio was calculated for each subject by dividing the amount of PTC solution consumed by the total liquid ingested. Thus a preference ratio of 0·5 indicates no preference, whereas a value less than 0·5 indicates avoidance. An inverse relationship of PTC taste sensitivity and preference ratio between 0·0 and 0·5 was inferred. To control for possible position preferences, a mean preference ratio for each 2 day period was computed. These data were transformed (Arcsin $\sqrt{\%}$) before statistical analysis.

The threshold concentration for a subject was defined as that concentration at which the subject's preference ratio was below 0·20 and remained below that value for all higher concentrations. The resulting threshold concentration distribution for each of the strains is presented in Fig. 1. It is interesting that the mode of the threshold distribution for BALB mice occurs at a concentration similar to that reported for human non-tasters[6]. Although qualitatively different, the mode of the threshold distributions of the other four strains occurs at a lower concentration than that for human tasters.

The mean preference ratios (untransformed) for each strain as a function of concentration are presented in Table 1. Transformed preference ratio data were subjected to analysis of variance, repeated measures design. Highly significant effects due to concentration ($F=157·5$, $P<0·005$, df$=12/480$) and strain by concentration interaction ($F=2·495$, $P<0·005$, df$=48/480$) were observed. These results suggest that BALB mice taste PTC at lower concentrations than the other strains. Although olfaction may have a role in the avoidance of PTC solutions, additional research has indicated that odour alone could not account for the observed differences.

Before the initiation of a genetic analysis of the strain difference in PTC taste sensitivity, we tried empirically to identify a concentration which yields maximum discrimination between "taster" and "non-taster" strains. For this purpose, the C57Bl strain was selected as representative of non-tasting strains. Three groups, each consisting of ten members of this strain and ten members of the BALB strain, were presented tap water and a single concentration of PTC solution in the two-choice situation for 12 days. On the basis of within-strain reliability, the subject's mean preference ratio on days 9 and 10 was used as the measure of taste sensitivity. Little or no difference was found between the strains at concentration five (1·6 mg/l.). At concentration six (3·2 mg/l.), most BALB mice avoided the PTC solution. In contrast, C57Bl mice began avoiding at concentration seven (6·4 mg/l.). Two other groups of ten BALB and ten C57Bl mice were tested at concentrations 6·25 and 6·5 (3·8 and 4·5 mg/l. respectively). Because the largest strain difference was obtained at concentration 6·5, this part of the experiment was repeated. On the basis of these results, the mean preference ratio on days 9 and 10 at concentration 6·5 was chosen as the phenotype for genetic analysis.

Corresponding data were obtained from additional members of the two parental strains and their F_1, backcross, F_2 and F_3 generations. There were several unusually high scores, which indicated almost perfect discrimination between PTC and tap water, but which resulted in preference rather than avoidance. To maintain an interpretation of these data consistent with that applied to the results of the initial investigation, the rejection rule of Anscombe and Tukey[7] was applied to these data. (The selection of a value of P (the percentage chance one is willing to take of rejecting an observation which is valid) of 2·5 per cent led to the rejection of one BALB, two B_1, one B_2, two F_2 and one F_3 subjects whose untransformed preference ratios were 0·951, 0·957, 0·980, 0·981, 0·973, 0·976 and 0·904 respectively.) The distribution of preference ratios of the remaining subjects in each generation is shown in Fig. 2. The bimodality observed in the B_2, F_2 and F_3 generations suggests single-locus determination with dominance for avoidance. The method of Collins and Fuller[8] was applied to these data to test the suitability of the single locus model. In general, the expected frequency within each preference ratio class interval of the segrating generations was calculated from the corresponding frequencies in the isogenic groups. These expected frequencies are also indicated in Fig. 2. None of the χ^2 values differed significantly from that predicted by the single locus model.

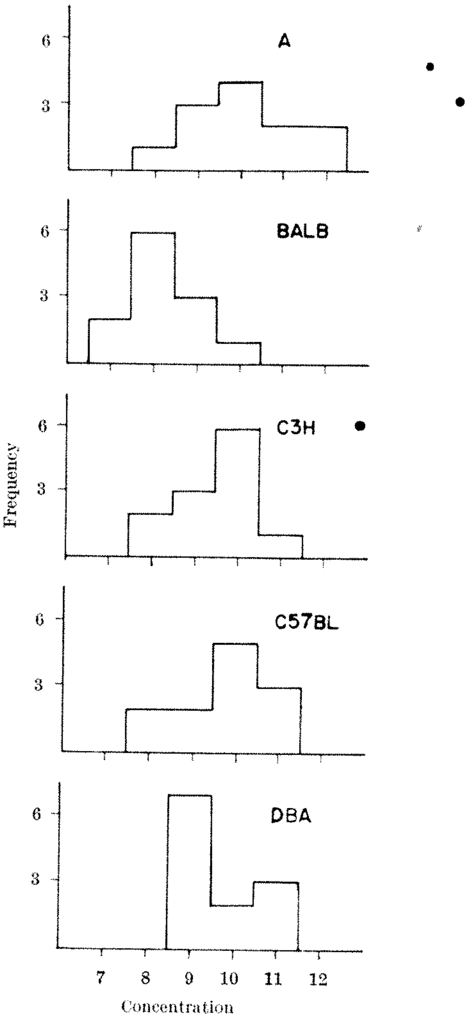

Fig. 1. PTC taste threshold concentration distributions.

To analyse the data of this experiment as a threshold character, a preference ratio of less than 0·20 was used as a criterion for tasting. The method of Collins and Fuller

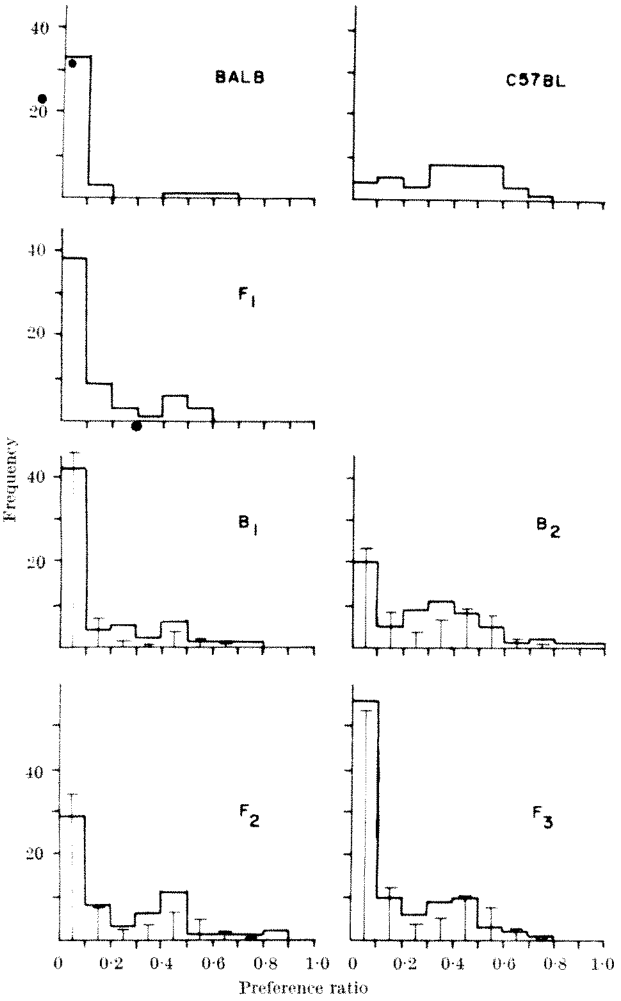

Fig. 2. Distribution of mean PTC preference ratios on days 9 and 10 at concentration 6·5 for each of two inbred strains and their derived generations. For each segregating generation the expected distribution based on a single locus model is indicated by vertical lines. (N = 39 BALB, 40 C57Bl, 60 F_1, 62 B_1, 63 B_2, 62 F_2 and 97 F_3 subjects.)

was also applied to these data and no significant χ^2 value was found. These results support the hypothesis of determination by a single locus.

Wright's methods[9] for estimating the number of independently segregating Mendelian units were applied to the preference ratio data. Although different assumptions are required for each of the estimates and although data from different generations are used, the resulting estimates are in very close agreement (1·04, 1·05 and 1·07). Finally, the method suggested by Scott and Fuller[10] for estimating the number of loci involved in a threshold character was applied to the preference ratio data. This method, which uses only first degree statistics, is especially suitable for characters in which the distributions of the isogenic parental strains are not clearly dichotomous. Resulting values were highly consistent with single locus determination.

Although the methodology used precludes its proof, it is very likely that individual differences in taste sensitivity to PTC in mice are due largely to a single autosomal locus. The existence of this polymorphism, similar to that in man, raises interesting questions about the maintenance of polymorphisms across a wide phyletic distribution. Although Fischer[2] has discussed the possible fitness value of taster and non-taster phenotypes and has proposed that this polymorphism may be maintained by heterozygote advantage, the adaptive significance of individual differences in taste sensitivity to PTC and related compounds remains unknown.

Bark Beetle Pheromones

KINZER *et al.*[1] have recently reported the identification and synthesis of the bicyclic compound, frontalin. We wish to question the validity of some of their conclusions in the light of earlier work by this group at the Boyce Thompson Institute and Battelle Memorial Institute.

In connexion with the volatiles from oleoresin in the population aggregating pheromone of *Dendroctonus frontalis* they state: "The attack generates host odours as the beetles penetrate the phloem tissue and stimulate resin flow" and "the response to the synthetic attractant [frontalin] was increased by adding oleoresin freshly tapped from *Pinus taeda*". Yet in another article[2] they state: "The results demonstrate the existence of a mechanism which enables certain bark beetle species [*D. frontalis*] to release a population aggregating pheromone immediately upon arrival at a new host, prior to actual infestation". In another report[3], they state for the same insect: "At peak attractiveness of a tree, relatively few of the attacking beetles had begun gallery construction. The majority had barely reached the phloem tissue". Thus whereas two papers reported that the attractants are produced before the xylem oleoresin is released, in ref. 1 Kinzer *et al.* state that xylem oleoresin, which the beetle must release through its boring activity, is a synergist to the identified compound, frontalin. If frontalin is attractive only in mixture with oleoresin, then their observation that the population aggregating pheromone is released "immediately upon arrival at a new host, prior to actual infestation" must be in error. If this observation is not in error, however, then the role of frontalin in the aggregation pheromone is not as clear as they state.

A fraction attractive to pedestrian *D. frontalis* beetles in the laboratory bioassay has been isolated by Renwick and Vité[4], but this fraction could not be identified because "an estimated million beetles seemed barely enough to yield a single milligram of this substance"[5]. Subsequently, Kinzer *et al.*[1] isolated and identified a compound from *D. brevicomis* males which had the same ring structure (bicyclic ketal) as did brevicomin, previously isolated from *D. brevicomis* females by Silverstein *et al.*[6]. The structure of brevicomin was announced in November 1967 (ref. 7). The unknown compound in *D. frontalis* females was then found to have the same gas chromatographic properties as the bicyclic ketal identified from *D. brevicomis* males which was named frontalin (contrary) to the usual practice of assigning trivial names descriptive of the source from which they were identified). The compound was then synthesized, but "walking beetles [*D. frontalis*] failed to show any reaction to the new material"[5], in contrast to earlier bioassay results with that fraction isolated from female *D. frontalis* hindguts[4]. When frontalin was mixed with oleoresin, however, it was found to be active in the field[1]. We question the rationale of a procedure by which a compound is identified from the males of one species, searched for and found to be present in the females of another and then designated as the "principal component of the aggregating pheromone"[1]. Any number of similar or different compounds might be more significant as attractants for *D. frontalis*.

In their field tests, Kinzer *et al.* compare the relative attractiveness of frontalin to crushed males and females[1]. Crushed insects can hardly be considered a natural phenomenon, particularly in view of previously published work in which they show that female-infested billets and trees under attack are very attractive[3]. To our knowledge, the relative attractiveness of crushed beetles combined with oleoresin to infested billets and/or trees under attack has not been established. We would conclude that such a tree or billet is the more logical and meaningful control than crushed males and females. Compounds present in the emerged insect, in, for example, their hindguts, plus xylem oleoresin[1] do not necessarily add up to the pheromones of these insects. Many other sources of compounds are possible; for example, compounds produced through feeding, compounds in the bark and phloem, and compounds in the xylem not associated with oleoresin.

Their attempt to associate *trans*-verbenol with the pheromone of *D. frontalis* is doubtful[1]. In two series of three 10 min field tests, the following materials were exposed: frontalin, *trans*-verbenol, and oleoresin; frontalin and oleoresin; *trans*-verbenol and oleoresin; frontalin; oleoresin; and crushed male and female beetles and oleoresin. Apart from the brief exposure times and their dubious use of crushed beetles as a control (see earlier remarks), no test results were shown for a mixture of frontalin and *trans*-verbenol, nor was the mixture of frontalin, *trans*-verbenol and oleoresin compared with the mixture of frontalin and oleoresin and the mixture of *trans*-verbenol and oleoresin in either series. Thus no assessment of the function of *trans*-verbenol can be made from their data.

In reporting the identification of frontalin, they state that "two analogous compounds have been previously identified from natural sources"[1]. These two "analogous compounds", however, should not be considered in the same light, biologically speaking, because one was isolated from hop oil and the other from *D. brevicomis* females, certainly a close relative of *D. brevicomis* males. Silverstein *et al.*[6] actually identified two bicyclic ketals from the frass of *D. brevicomis* females (exo- and endo-brevicomin).

Actin-like Properties of Colchicine Binding Protein isolated from Brain

THE isolation from mammalian brain of a protein with properties similar to those of muscle actomyosin was recently reported[1] and it was suggested that the protein was composed of actin-like and myosin-like subunits. There have also been references[2] to the possibility that colchicine binding protein isolated from the microtubules of sea urchin sperm tails[3], mitotic spindles[4,5] and the cilia of *Tetrahymena*[6] may be composed of an actin-like protein. The ability to bind colchicine also seems to be a characteristic of the microtubules of the central nervous system[7] and a colchicine binding protein has been isolated from mammalian brain[8]. It was therefore of interest to isolate colchicine binding protein from brain and test its actin-like properties.

Colchicine binding protein was isolated from porcine brain by the batch procedure[8]. Ammonium sulphate was removed from the final preparation by passage through 'Sephadex *G*-25'. Myosin was prepared from fresh, long back muscles of the cat by a modification of the method of Asai[9,10]. Brains were delivered in ice within a few hours after removal from the animals. The leptomeninges and the associated blood vessels as well as the choroid plexus were removed before extraction. Isolation of the protein was followed by ^{3}H-colchicine binding studies performed essentially as described by Weisenberg *et al.*[8]. Before the viscosity and adenosine triphosphatase (ATPase) experiments the protein was passed through 1·5 × 10 cm columns of 'Sephadex *G*-25' to remove the GTP used in the isolation procedure. ATPase activity was assayed by the Marsh procedure[11] adapted for the determination of as little as 0·1 μg of P_i released from ATP (for details see Table 1).

Table 1. EFFECT OF COLCHICINE BINDING PROTEIN ON THE ATPase ACTIVITY OF MUSCLE MYOSIN

	μmoles Pi/mg protein/min		
Cation	Myosin	Colchicine binding protein	Myosin and colchicine binding protein
Mg^{2+}	0·024	0	0·65
Ca^{2+}	0·37	0	0·48

The myosin was isolated from cat striated muscle and the colchicine binding protein from porcine brain. Phosphate release was calculated on the basis of the amount of myosin in the assay medium. The incubation medium (1 ml.) contained 0·03 M imidazole-HCl (*p*H 6·8), 0·06 M KCl, 5×10^{-4} M ATP, 10^{-3} M Mg^{2+} or Ca^{2+}, 10^{-4} M ouabain and 0·01 mg of myosin and 0·1 mg of colchicine binding protein. Incubation was for 30 min at 37° and was terminated by the addition of 0·4 ml. of 20 per cent trichloroacetic acid. The blanks were protein solutions inactivated by boiling for 3 min or by trichloroacetic acid treatment before the addition of ATP.

Protein was determined by the procedure of Lowry *et al.*[12], with bovine serum albumin as standard.

Colchicine binding protein increased the Mg^{2+}-ATPase activity of muscle myosin approximately twenty-seven-fold (Table 1); the Ca^{2+}-activated ATPase activity of the myosin was enhanced only slightly. The Mg^{2+}-stimulated activity of the myosin increased from levels much below that for the Ca^{2+} activation to values above it. Addition of colchicine binding protein to myosin resulted in an increase in the relative viscosity of the myosin and a marked increase in sensitivity to ATP (Fig. 1). The addition of ATP to the mixture of myosin and colchicine binding protein resulted in a decrease in relative viscosity which increased again over a period of 30–60 min. GTP did not have this effect.

Disc gel electrophoresis (Canalco apparatus) performed in 7·5 per cent acrylamide gel containing 8 M urea showed a single major band similar to that described previously[8]. A sedimentation study of colchicine binding protein in the model E Beckman analytical ultracentrifuge revealed a single peak ($s_{20,w}$ 8·7) with negligible contamination. An analysis for 80 min after reaching speed confirmed its homogeneity. Similarities between colchicine binding protein and actin have been described[2] and recently reviewed[6]. These include the characteristics of extraction at low ionic strength, molecular weight, amino-acid composition, electrophoretic mobility and nucleotide binding properties.

Our study demonstrates that colchicine binding protein from brain reacts with muscle myosin and that the interaction occurs not only between proteins from different organs but also from different species. Its effects on the ATPase activity and viscosity of the muscle myosin indicate that it has actin-like properties. It may well be, therefore, that microtubules in brain function in the saltatory transport of material and vesicles from their site of formation in the cell body to their site of utilization at the synaptic endings (compare ref. 2).

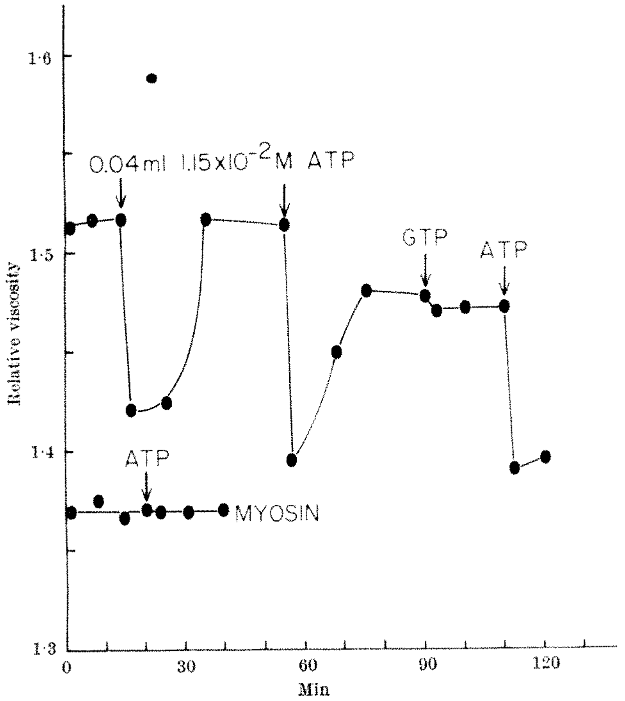

Fig. 1. Effect of ATP on the relative viscosity of myosin alone (lower curve) and in combination with colchicine binding protein (upper curve). Measurements were performed at 21° in a Cannon–Ubbelohde dilution viscometer size 50 on a minimum volume of 6 ml. The viscosity of protein solutions relative to the buffer (η_{rel}) was determined in 0·05 M Tris-HCl (*p*H 7·2)—0·6 M KCl. The response to ATP (η_{rel} ATP) was measured by the addition of 0·04 ml. of $1 \cdot 15 \times 10^{-2}$ M ATP in the same buffer adjusted to *p*H 7·2. The arrows indicate times of addition of 0·04 ml. $1 \cdot 15 \times 10^{-2}$ M ATP or 0·05 ml. 5×10^{-3} M GTP. Myosin (2 mg/ml.) was isolated from cat striated muscle and colchicine-binding protein (0·70 mg/ml.) from porcine whole brain. The relative viscosity of the colchicine binding protein alone was approximately 1.

Population Analysis of Somatosensory Thalamus in the Cat

THE responses to both natural and electrical stimulation of peripheral structures, and to electrical stimulation of the cerebral cortex, were determined for a representative sample of forepaw-responsive neurones in the nucleus ventralis posterolateralis (VPL) of the cat thalamus. Information from all the cells studied permits a reconstruction of the behaviour of the total population of neurones responding to a given input (that is, forepaw stimulation). The spatio-temporal distribution of unit neuronal activity occurring within the somatosensory thalamus following application of discrete stimuli to the body surface, once reconstructed, can be understood in terms of the contributions of various kinds of neuronal elements to the overall population response.

Relatively few cells (ten to twenty) could be isolated and studied in any one animal; it was necessary to synthesize the total population by pooling data from individual animals, with unit stereotaxis locus providing a basis for collating the data. Correspondence between the stereotaxic locus of units and actual regions of the nucleus in which they were located was checked by gross potential mapping of the forepaw responsive area in each animal and by histological confirmation of penetration positions in some cases. An imaginary grid was constructed, its boundaries being the minimal rectangular volume enclosing the VPL (established by planes at A8 and A11, L5 and L8, and H3 and H-2·5). Vertical microelectrode penetrations were made through this volume of tissue at millimetre intervals on the grid, and each neurone encountered (regardless of the particular animal in which it was found) was represented on the grid at its stereotaxic locus. Data were collected from each unit in the form of extracellular recordings of its discharge of impulses evoked by peripheral and central stimulation, utilizing NaCl-filled glass micropipettes of 1·5–2·0 μm tip diameter.

Attention was given in the analysis to a correlation of the response properties of neurones with their position within the volume of tissue studied. The aggregation of neurones sharing a particular natural stimulus sensitivity or possessing receptive fields of comparable extent has been noted by other investigators studying dorsal column nuclei (DCN)[4,7,10] and somatosensory cortex[6]. One would suppose that a separation of hair and touch sensitive cells begun in the DCN would be maintained as projections pass through the thalamus on the way to the cortex, where hair and touch cells also reside preferentially in different regions. Also, one might expect to see wide-field neurones at the thalamic level which correspond to those observed in pericruciate regions of cortex[12] if the convergence of input involved in elaborating these wide fields occurs at the thalamic rather than the cortical level. For these reasons, the reconstructed population of thalamic neurones was examined for evidence of aggregation of neurones according to their natural stimulus sensitivities and/or their receptive field sizes.

Cats were anaesthetized with α-chloralose (60 mg/kg) and paralysed with 'Syncurine' or 'Flaxedil'. Stimulus pulses were administered through bipolar needle electrodes placed in the central footpad of each of the four paws to evoke discharge of, isolate, and identify thalamic cells. Bipolar ball-tipped stimulating electrodes on the cortical surface in postcruciate, coronal and postdimple areas were used to study cortical influences on peripherally evoked thalamic activity and to identify cortical projection areas of thalamic cells by antidromic activation. Units isolated in response to electrical stimulation of the contralateral forepaw (CFP) were then tested for responsiveness to electrical stimulation of the other appendages. Their natural stimulus was determined, including modality, location and extent of receptive field. Finally, responses to electrical stimulation of CFP and other inputs were photographed for measurement of unit response characteristics, including latency and number of spikes per discharge. Other functional properties (threshold stimulus intensity, ability to follow repetitive stimuli at various rates, and changes in excitability arising from conditioning shocks applied to the cortex) were assessed directly.

Units were partitioned into an *s* set, responding only to stimulation of CFP, and an *m* set, responding to CFP and at least one other appendage as well. They were further classified according to their natural stimulus modality, using operational definitions of hair and touch sensitivity. Hair cells discharged in response to deflexion of a few hairs by air puffs or with a forceps, while touch cells failed to discharge to such stimuli but responded to light taps applied directly to the skin. Other types of cells (claw sensitive, nociceptive, vibration sensitive, and so on) were also found. In forty-six experiments on chloralose-anaesthetized animals, 640 neurones were isolated within the volume of tissue under consideration and studied. Of these, approximately 30 per cent were classified as *m* neurones. These neurones usually had large but discontinuous receptive fields with portions in the form of "gloves" and "stockings" on the contralateral forelimb and one or more other limbs. They were found scattered throughout the nucleus, often in the same tracks with *s* neurones (even in the CFP focus defined by gross potential mapping), although they predominate in a particular region. Various combinations of effective inputs were found for *m* neurones, such as both forelimbs, both contralateral limbs, or all four limbs. Most of them had ipsilateral inputs. The *s* neurones accounted for about 68 per cent of the total population. (An additional seventeen neurones were lost before the extent of their receptive fields could be determined and were classified as responding to CFP at least.) The *m* and *s* sets were compared with respect to their composition in terms of the natural stimulus sensitivities of their constituent elements; for both subsets the hair cells outnumber the touch cells, but there is a higher proportion of hair cells among the *s* set (50 per cent) than the *m* set (30 per cent). Hair and touch cells together account for 70 per cent of

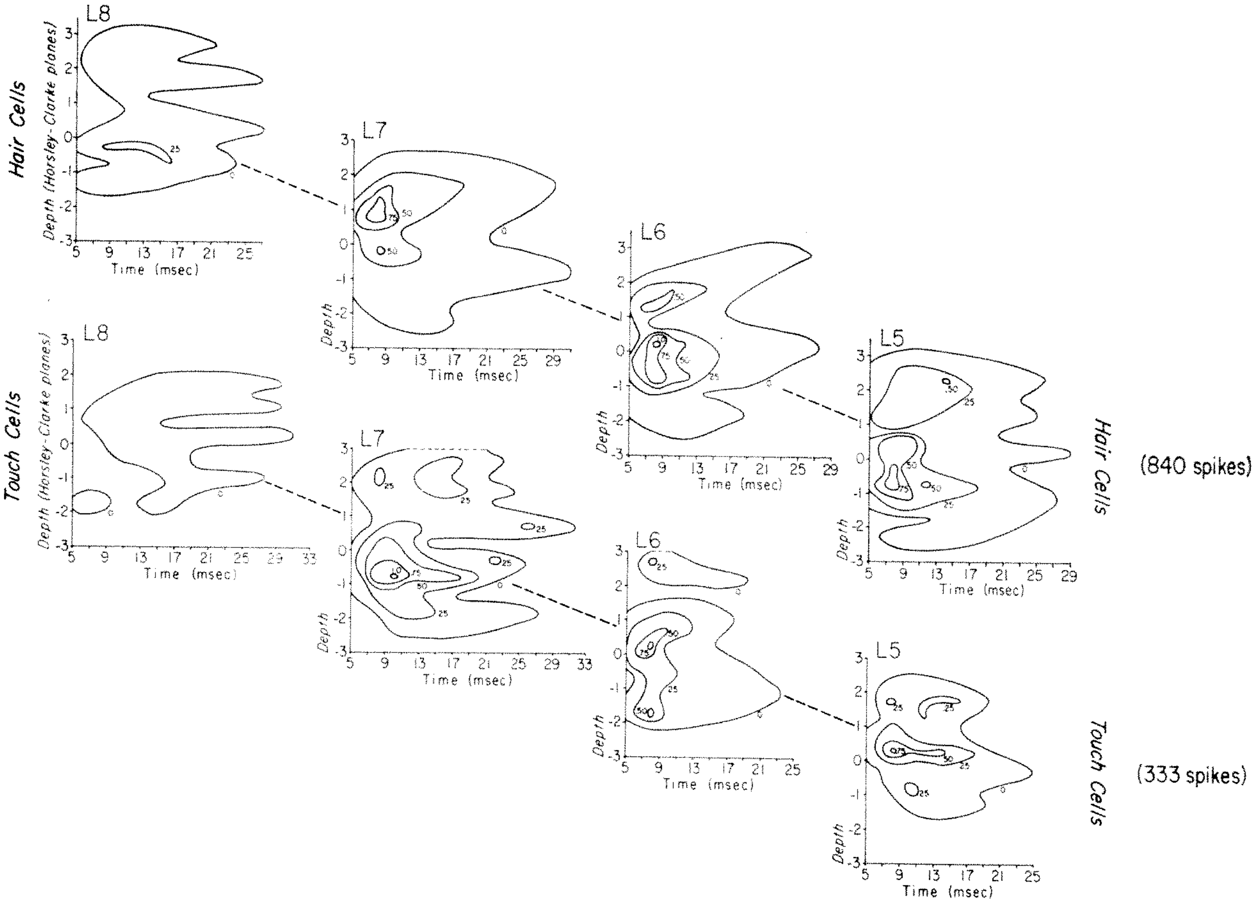

Fig. 1. Spike density plots for activity sustained by hair cell and touch cell subsets in response to stimulation of contralateral forepaw (0·1 ms, 7 V pulse). Each plot in the series of four for each subset depicts spike distribution as a function of depth and time in a particular parasagittal plane, moving from L5 (most medial) at the right to L8 (most lateral) at the left. Information about the anterior–posterior distribution of spike activity is unfortunately lost in these plots; all spikes occurring in a particular parasagittal plane were treated as if they had been found in a single "compressed penetration at the corresponding distance from the midline, no account being taken of where they occurred along the A–P axis. (This information is available, but not as useful as their distribution along the M–L axis.) Contour lines enclose regions in which the spike density is at 0·0, 0·25, 0·50 and 0·75 levels compared with that at the point of maximum density indicated as 1·0. Plots start at 5 ms after stimulus presentation. Depth coordinates range from 3 mm above horizontal zero to 2·5 mm below it. It is helpful to read each plot as if one were "looking through" the nucleus from behind along the corresponding plane; imagine observing changes in number and depth distribution of spikes as time elapses after the stimulus.

the *s* neurones, but for only 42 per cent of the *m* neurones. The latter set contains in addition a number of cells which were unresponsive to all forms of natural stimuli applied (11 per cent) and a group which responded only to noxious stimuli (14 per cent).

The population was examined for rostro-caudal, lateromedial, and/or dorso-ventral segregation of all the types of cells encountered; the absolute numbers of cells found within each region and the proportional contribution of each kind of cell to the total found in each region were both considered. The results indicate an aggregation of neurones according to stimulus sensitivities and according to receptive field size as nuclear organizational features in addition to somatotopy. Both hair and touch cells are most numerous ventrally, but hair cells cluster in the medial portion of the nucleus (A10, L5 and L6) whereas touch cells are scattered more diffusely throughout the central portion (A8–A10, L6 and L7). The *s* neurones are concentrated medially (A10, L5) and ventrally, while *m* neurones occur with greatest frequency in lateral, posterior regions (A8 and A9, L7 and L8) and are rather uniformly distributed in depth. In view of the caudal position of *m* neurones, it should be noted that the volume under study does not extend as far posteriorly as the posterior nuclear group of Poggio and Mountcastle[11], in which units possessing similar wide fields were also found. The *m* neurones I describe are within VPL, and are not predominantly pain-sensitive like those described for the posterior nuclear group by Poggio and Mountcastle. Moreover, at least a representative sample of them were found to project to areas within the S1 somatosensory receiving area of the cortex.

The conclusion that touch and hair cells, and *s* and *m* neurones, are segregated within the nucleus is given additional support by comparison of time-depth spike density plots depicting the time course and spatial distribution of evoked activity typical of each subset. These spike density maps should be read like geographical contour maps; the spike discharge density contour lines are the equivalent of altitude or elevation indices, while the stereotaxic plane and the depth axis indicate where the observer is and the time axis indicates when—relative to the time of stimulus application—the discharge is being considered. For example, one might ask: In the L5 plane, at 0·0 depth corresponding to the midpoint of the nucleus, how intense is the discharge at 8·0 ms after stimulation?—and answer this by reference to the density plots. These plots show that the locus of maximum spike density, as well as the overall time course and distribution of discharge, differs for hair and touch cells and for *s* and *m* neurones. The region displaying peak density of activity in touch cells is located 1 mm lateral to that for hair cells (Fig. 1), and peak activity occurs later (by about 2 ms) for touch cells than for hair cells. Most activity in the extreme lateral portion of the volume, occurring still later, is supported by *m* neurones.

Subsets were also compared with respect to several other functional characteristics defined on the basis of their response to electrical stimulation of CFP and with respect to the effects produced by cortical stimulation. Mean first-spike response latency is shorter for hair cells (8·7 ms) than for touch cells (9·2 ms). Hair cells also have a lower threshold (1·03 units) and higher frequency following capability (31 per s) than do touch cells (1·26 units; 21 per s). The *m* set is characterized by longer first-spike latency (12·1 ms), lower mean threshold (1·04 units) and poorer frequency following (10 per s) than the *s* set (8·7 ms; 1·21 units; and 29 per s). Descending cortical influences were found to be exerted on all types of units encountered. The coronal area of cortex (that is, the S1 forepaw focus) was the best site for the evocation of synaptically mediated effects on the thalamic elements studied. Reports by others led to the expectation that thalamic touch cells would project to the coronal cortex while hair cells would project to pericruciate areas[6,8,12]; it was surprising to find both sets trans-synaptically influenced from the coronal cortex in similar numbers. When the spatial distribution of cortically influenced neurones was taken into consideration, however, cortically inhibited cells corresponded in distribution with hair cells and cortically excited cells with touch cells. Thus cortical influences seem to be distributed in accordance with organizational lines established through modality segregation.

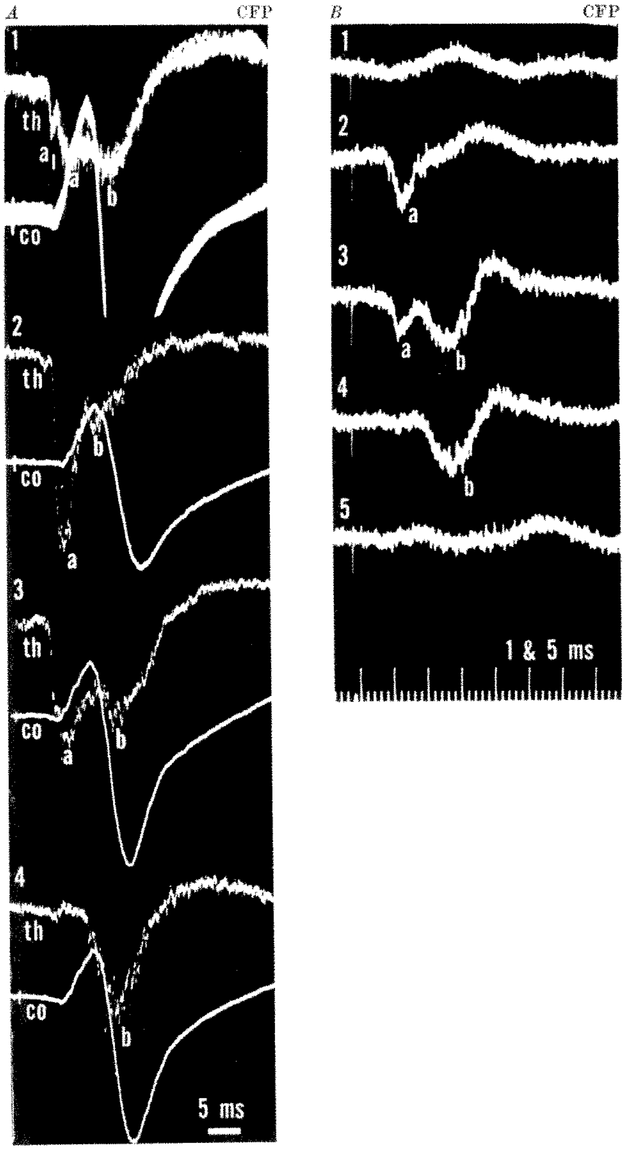

Fig. 2. Gross potential responses to stimulation of contralateral forepaw (0·1 ms, 7 V pulse), recorded through microelectrode with enlarged tip (indifferent lead clipped to scalp). In *A*, the upper trace of each pair is from the thalamus; the lower trace is from the coronal area of the cerebral cortex (S1 forepaw representation at the cortex). The thalamic recordings were taken during penetration at A8, L7. Note three components (a_1, *a* and *b*) of thalamic response which develop differently in depth. The a_1 component is probably pre-synaptic (lemniscal input); the early *a* component is probably identical with Mountcastle and Henneman's "localizing potential"[9], while the later *b* component may represent corticofugal activity or late activity from the periphery. In *B*, taken during penetration at A9, L7, the differential development in depth of *a* and *b* components is again illustrated; here, the *b* component is a positive–negative complex. In *A* and *B*, successive records were taken at 0·5 mm intervals in depth ranging from 1 mm above horizontal zero to 0·5 or 1·0 mm below it. Positivity is downward for thalamic records, upward for cortical records.

Gross potential records from regions within the volume of tissue studied reveal a compound response—an early positive wave, followed by a later positive or positive–negative wave—in response to CFP stimulation (Fig. 2). The position of the maximum amplitude early response establishes the CFP "focus" medially within the volume (in the L5 or L6 plane); the late wave is often more pronounced in lateral areas (L7 or L8). Because many of the units encountered could be influenced from the cortex, one interpretation of the late wave is that it reflects activity in elements which are driven (or inhibited) via a loop through the cortex, after the effective cortical sites are first activated from the periphery. Alternatively, the late wave may reflect a component of unit activity driven through a slowly conducting route from the periphery; the *m* neurones would probably support this activity, and the spinothalamic pathway would be the most likely route over which they would be driven (the "neospinothalamic" component of the spinothalamic system has been shown by anatomists to reach the region corresponding to the maximum concentration of *m* neurones within VPL[1-3,5]). Experiments involving tract sectioning and cortical ablations will be necessary to differentiate between these possibilities.

Distribution of ^{14}C-Thiosemicarbazide in the Rat Brain: an Attempt to localize Sites of γ-Aminobutyric Acid Production

IT is still not known whether γ-aminobutyric acid (GABA) is a "real" inhibitory substance in the mammalian central nervous system[1,2]. Before the role of GABA in inhibitory mechanisms can be understood, it is important to locate histochemically the sites of GABA metabolism.

Intrinsic GABA cannot be detected histochemically; nor can the enzymes involved in its production and breakdown be reliably located[3]. Moreover, attempts to locate extrinsically injected GABA-^{3}H have been unsuccessful because of impeded transport or enhanced breakdown of the radioactive compound[1]. We therefore attempted to locate one of the most powerful inhibitors of GABA synthesis—the convulsive drug thiosemicarbazide. Like other hydrazides, this drug inhibits the activity of enzymes dependent on vitamin B_6 including that of glutamate decarboxylase (GAD, 4.1.1.15), which is responsible for the formation of GABA[4]. Thus the distribution of thiosemicarbazide, at the height of symptoms induced by inhibition of GAD, might help locate the site of GAD activity, or at least the absence of thiosemicarbazide

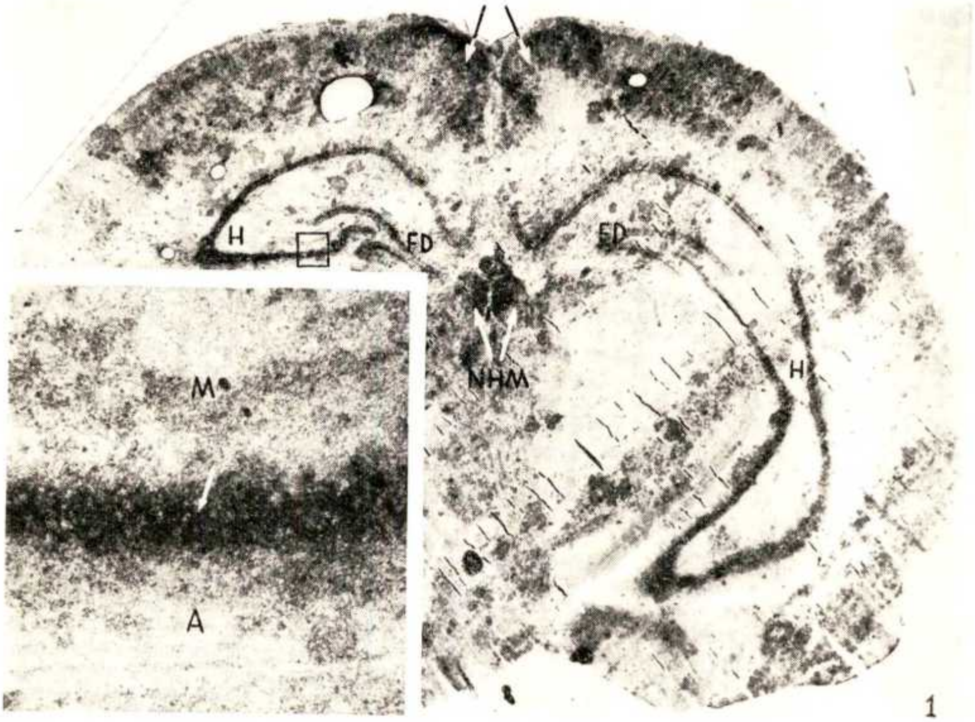

Fig. 1. Coronal section of rat brain, 90 min after two consecutive injections of TSC-^{14}C. Unstained autoradiogram of a cryostat section. H, Hippocampus; FD, fascia dentata; NHM, nucleus habenularis medialis. Arrows indicate cortical areas exerting a relatively strong reaction. Inset, enlarged detail of the hippocampus (the area in the rectangle). Note the heavy reaction in the layer of hippocampal pyramids; cell bodies (arrow) do not exert any reaction. A, Alveus; M, molecular layer.

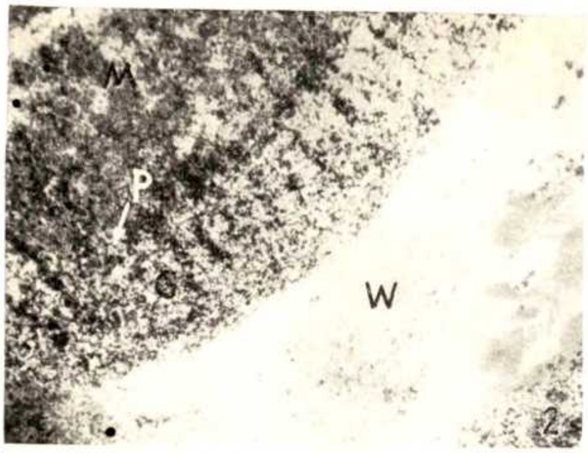

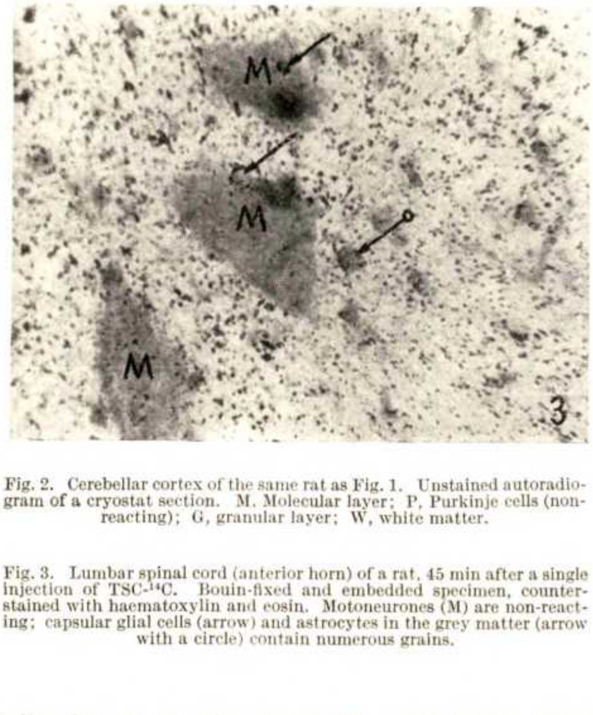

Fig. 2. Cerebellar cortex of the same rat as Fig. 1. Unstained autoradiogram of a cryostat section. M, Molecular layer; P, Purkinje cells (non-reacting); G, granular layer; W, white matter.

Fig. 3. Lumbar spinal cord (anterior horn) of a rat, 45 min after a single injection of TSC-^{14}C. Bouin-fixed and embedded specimen, counterstained with haematoxylin and eosin. Motoneurones (M) are non-reacting; capsular glial cells (arrow) and astrocytes in the grey matter (arrow with a circle) contain numerous grains.

binding by non-reacting structures might indicate those cellular elements that do not exert GAD activity. Such an approach is actually an adaptation of the principle described by Ostrovsky and Barnard[5].

Rats weighing 160 g were injected intraperitoneally with 5–20 mg/kg thiosemicarbazide-^{14}C (specific activity 10 mCi/mmole, obtained from the Central Isotope Institute, Budapest). Characteristic convulsions and lethal "jumps" appeared 45–120 min after injection. The animals were killed by decapitation and samples of the central nervous system (brain, medulla, cerebellum, spinal cord) as well as other tissues were either fixed on Bouin's solution and prepared for autoradiography in the usual way or were not fixed but frozen with dry ice, cut on a cryostat and applied to slides pre-coated with Kodak *AR*-10 stripping film, emulsion side up. The exposure time was 3–8 weeks; autoradiograms were developed in Kodak autoradiographic developer and some were counterstained with haematoxylin and eosin.

Fig. 1 shows a coronal section of the brain of a rat given two intraperitoneal injections of 10 mg/kg TSC-^{14}C, with an interval of 40 min between them, and then killed 90 min after the first injection. The heaviest reaction is confined to the hippocampus and fascia dentata chiefly in the layer of hippocampal pyramids (Fig. 1, inset); silver grains are, however, not found in the nerve cells themselves but are concentrated in the surrounding neuropil. Activity is high also in the nucleus habenularis medialis. There is a moderate reaction in the cortex, especially in the vicinity of the interhemispherical fissure.

Both the molecular layer and the granular layer of the cerebellum contain numerous silver grains (Fig. 2). The localization pattern of the reaction does not, however, conform to any of the neural elements but resembles more closely the glial structure. The reaction is slightly stronger around Purkinje cells, which are themselves devoid of any reaction both in pre-fixed and in non-fixed specimens. On the other hand, in deep cerebellar nuclei (and also in some of the brain stem nuclei, for example the substantia nigra and nuclei pontis) silver grains are located within the cytoplasms of nerve cells. Weak or virtually no activity can be seen in the white matter, although the glial cells in the white matter react if higher doses of TSC are used or if the animals are killed after a shorter time interval.

The nerve cells in the spinal cord do not contain silver grains, but capsular and other glial cells in both the grey and white matter contain numerous grains (Fig. 3). According to Curtis[2], GABA is not involved in spinal inhibitory mechanisms.

The gross distribution of silver grains reduced by TSC-^{14}C is in accord with the distribution of GAD and GABA anticipated on the basis of earlier biochemical and pharmacological studies (cerebellar cortex[2], hippocampus[2], substantia nigra[6]). While the concentration of silver grains in nerve cells (dentate nucleus, substantia nigra) and in the neuropil surrounding them (hippocampus) is consistent with current views, it is striking that Purkinje cells do not exert any reaction. Proteins sensitive to TSC are undoubtedly more widespread than GAD, so the apparent localization of TSC in glial cells of the cerebellar cortex may be partly due to binding of the drug to other B_6-dependent enzymes. The possibility cannot be excluded, however, that, at least in this area, GABA is produced by glial cells, perhaps in order to be taken up by nerve terminals and/or nerve cells in a second step.

Natural Selection and the Concept of a Protein Space

SALISBURY[1] has argued that there is an apparent contradiction between two fundamental concepts of biology— the belief that the gene is a unique sequence of nucleotides whose function it is to determine the sequence of amino-acids in a protein, and the theory of evolution by natural selection. In brief, he calculated that the number of possible amino-acid sequences is greater by many orders of magnitude than the number of proteins which could have existed on Earth since the origin of life, and hence that functionally effective proteins have a vanishingly small chance of arising by mutation. Natural selection is therefore ineffective because it lacks the essential raw material—favourable mutations.

I should like to look at the problem from a different point of view. I shall assume that mutations, while not random in a chemical sense, are random as far as their chances of improving the function of the corresponding proteins are concerned. I shall also assume that evolution has occurred either by the natural selection of favourable mutations or by the chance fixation by genetic drift of selectively neutral mutations. The justification for making these assumptions is that no sensible alternatives have been suggested and that no evidence exists at the moment to invalidate them. If these assumptions are true, what can we say about the frequency and distribution of amino-acid sequences which are functional, either as enzymes or in some other way?

The model of protein evolution I want to discuss is best understood by analogy with a popular word game. The object of the game is to pass from one word to another of the same length by changing one letter at a time, with the requirement that all the intermediate words are meaningful in the same language. Thus WORD can be converted into GENE in the minimum number of steps, as follows:

WORD WORE GORE GONE GENE

This is an analogue of evolution, in which the words represent proteins; the letters represent amino-acids; the alteration of a single letter corresponds to the simplest evolutionary step, the substitution of one amino-acid for another; and the requirement of meaning corresponds to the requirement that each unit step in evolution should be from one functional protein to another. The reason for the last requirement is as follows: suppose that a protein A B C D . . . exists, and that a protein a b C D . . . would be favoured by selection if it arose. Suppose further that the intermediates a B C D . . . and A b C D . . . are non-functional. These forms would arise by mutation, but would usually be eliminated by selection before a second mutation could occur. The double step from a b C D . . . to A B C D would thus be very unlikely to occur. Such double steps with unfavourable intermediates may occasionally occur, but are probably too rare to be important in evolution.

This is a model of the way in which one gene may change into another. An increase in the number of different genes in a single organism presumably occurs by the duplication of an already existing gene followed by divergence. If so, it remains true that new genes arise as modifications of pre-existing ones.

It follows that if evolution by natural selection is to occur, functional proteins must form a continuous network which can be traversed by unit mutational steps without passing through nonfunctional intermediates. In this respect, functional proteins resemble four-letter words in the English language, rather than eight-letter words, for the latter form a series of small isolated islands in a sea of nonsense sequences. Of course, this is not to deny the existence of isolated island proteins, analogous to the four-letter words ALSO and ALTO.

It is easy to state the condition which must be satisfied if meaningful proteins are to form a network. Let X be a meaningful protein. Let N be the number of proteins which can be derived from X by a unit mutational step, and f the fraction of these which are meaningful, in the sense of being as good as or better than X in some environment. Then, if $fN > 1$, meaningful proteins will form a network, and evolution by natural selection is possible. In estimating N it is necessary to distinguish two classes of mutations: (i) substitutions of single amino-acids, and additions or deletions of small numbers of amino-acids, making only a small change to the protein; and (ii) mutations producing a major change in amino-acid sequence, such as frame shifts and intramolecular inversions.

Mutations of the former type are much more likely to give rise to meaningful proteins than the latter. In the same way, a single random letter substitution in a meaningful word is more likely to give rise to a meaningful word than the simultaneous alteration of all the letters. Although frame shift mutations are known to occur, it is not clear whether they have ever been incorporated in evolution. It is therefore better to take N as the number of possible substitutions of single amino-acids. If all substitutions were possible in a single mutational step, N for a protein of 100 amino-acids would be 1,900. In practice the genetic code limits N to approximately 10^3.

Hence f must be greater than 1/1,000. It does not follow that the fraction of all possible sequences which are meaningful need be as high as 1/1,000. It is probably much lower. There is almost certainly a higher probability that a sequence will be meaningful if it is a neighbour of an existing functional protein than if it is selected at random. In fact, in treating N as the number of amino-acid substitutions rather than as the total number of possible mutational steps, it was in effect assumed that a random sequence has a negligibly small probability of being functional; this assumption will be confirmed if it turns out that frame shifts are rarely or never incorporated in evolution.

Suppose now that we imagine all possible amino-acid sequences to be arranged in a "protein space", so that two sequences are neighbours if one can be converted into another by a single amino-acid substitution. Then the requirement that $fN > 1$ requires that the "density" of functional proteins in certain regions of the space must be quite high—perhaps greater than 1/1,000. This agrees with Salisbury's conclusion that proteins, and hence the genes that determine them, cannot be as unique as all that. As a convinced Darwinist, I published[2] the conclusion that $fN > 1$ when little was known about the frequency of amino-acid substitutions in evolution. Since then evidence has accumulated (for a review, see King and Jukes[3]) that many substitutions are either selectively neutral or at least make comparatively minor changes in the function of proteins.

If $fN > 1$, no quantitative difficulty arises in explaining the evolution of proteins by natural selection. A difficulty nevertheless remains in explaining the origin of life—that is, in explaining the origin of the first functional proteins together with the genetic mechanism for producing them. If it were true that only a minute fraction of possible amino-acid sequences have even the slightest enzymatic activity, it would be difficult to understand how the first proteins arose. I do not want to discuss the problem of the origin of life, but only to point out that it is a quite different problem from that of the mechanism of evolution.

Some questions about molecular evolution can be formulated more clearly in terms of a protein space. For example: (i) Are all existing proteins part of the same continuous network, and if so, have they all been reached from a single starting point? Possible alternatives are that there are two or more distinct networks, or that there is one network with multiple starting points. (ii) How often, if ever, has evolution passed through a non-functional sequence? If so, has this been achieved by the random walk of genes rendered redundant by duplication, or by the chance concurrence of two or more mutations? (iii) What fraction of the functional network has already been explored in evolution? (iv) What fraction of potentially useful proteins are inaccessible?

Book Reviews

DETACHMENT AND INVOLVEMENT

Psychiatry in a Changing Society

Edited by S. H. Foulkes and G. Stewart Prince. Pp. xviii + 211. (Tavistock: London, October 1969.) 50*s*.

THIS volume is a byproduct of its senior author's year of office as chairman of the Psychotherapy and Social Psychiatry Section of the Royal Medico-Psychological Association (the organization to which nearly all British psychiatrists belong). As Dr Foulkes explains in his introduction, he took office at a time when there was vigorous discussion about the future of this section: in particular, about the desirability of separating its two principal components.

One school of thought, expressed in a lucid opening chapter by E. H. Hare, argues that the term "social psychiatry" has come to be so vague and all-embracing as to serve little purpose. Hare points out that some writers—notably Maxwell Jones—have used this term to refer to methods of treatment which enlist the contribution of members of a social group; others—notably Sir Aubrey Lewis—have emphasized the need for research designed to identify and measure the influence of social factors on the incidence and outcome of mental disorders.

Foulkes makes it very clear where his own sympathies lie. He vigorously rejects Hare's contention that "between psychotherapy and social research there is a deep, almost a fundamental, distinction". As he puts it: "The philosophy behind this concept of social psychiatry is that of an impartial science, incompatible with participation in or motivation for change". He believes that emotional and rational motivations determine the behaviour of those colleagues who disagree with him, preferring, to what he pejoratively calls objective psychiatry, his own brand of personal psychiatry: "The latter is a dynamic pursuit, entailing involvement and change in one's own person, and threatening values and attitudes. There is resistance against such change. The techniques of segregation, isolation, detachment and non-involvement are clearly preferred".

Many social scientists would contend that only by introducing an element of detachment and non-involvement can they guard against the self-deceptions which so readily accompany subjective impressions. Their doubts on this score can only be intensified by some of the *obiter dicta* in Foulkes's closing chapter, such as: "The concept of scientific detachment is outdated. . . . We must get away from a false impartiality in favour of a conscious participation in the service of humanity".

There is an important difference of opinion here about the proper content and methods of research in social psychiatry; but the argument presented is a rather one-sided one. Most of the book consists of essays by seven guest speakers, none of them psychiatrists, who addressed the section during Foulkes's year as chairman. Their contributions are interesting and diverse; Professor and Mrs Fortes report on the apparent increase in psychoses among the Tallensi people in Northern Ghana, during a period of 30 years; Dr Menzies describes her method of carrying out a study of nurse training in a teaching hospital; Dr M. R. A. Chance gives a detailed account of the application of techniques of ethological observation and analysis in the study of primate behaviour.

Of these papers, that by Menzies corresponds most clearly to Foulkes's concept of personal involvement in the social interactions which are being studied. Norbert Elias, a sociologist who writes on "Sociology and Psychiatry", contrasts the paradigms of "Homo psychiatricus" (who tends to be viewed as if in isolation from his fellows) and of "Homo sociologicus". He urges that more use should be made of the conceptual model which sees men as open systems, in which both events in their private histories (the usual concern of psychiatrists) and influences arising from their social interactions (the usual concern of sociologists) are each given due weight as determinants of behaviour. In his view, only Foulkes's own group analytic approach succeeds in fully exploiting both individual and group factors in therapy.

Paul Halmos, a social psychologist, contributes a refreshingly disquieting essay entitled "Psychology and the Ideology of Progress". This starts by recalling the familiar antithesis between vitalistic and mechanistic psychologies, but soon becomes more particular by focusing on the question: does the infant's experience of "good mothering" consist only of a finite, artificially reproducible number of sensory impressions—or is there more to it than that ? In this chapter, as in the book as a whole, the interest lies in the questions which are raised rather than in any claim to have discovered the answers.

G. M. CARSTAIRS

VIRUSES REVEALED

The Chemistry and Biology of Viruses

By Heinz Fraenkel-Conrat. Pp. x + 294. (Academic Press: New York and London, September 1969.) 84*s*.

THE study of virology as a biological science falls naturally into two parts. First, there is the nature of the complete virus particle, its chemistry and macromolecular structure; and second, there is the manner in which the virus interacts with host cells to give an infected complex. Professor Fraenkel-Conrat's concise and readable book covers both of these aspects, although approximately three-quarters of his book are concerned with the structure of viruses. It is difficult to write a textbook in a rapidly changing field such as virology, but in this case the author and publishers have chosen to produce the book in less than a year, an achievement well in evidence from the many recent references to research literature.

The book has been written to provide an introduction to virology both for students in the biological sciences and for research workers who are seeking to broaden their horizons, and both groups will benefit greatly from the wealth of interesting information presented. The experimental observations are explained and interpreted particularly well, the bench work being clearly related to the more formal model. Thus in a section describing methods of controlled degradation of viruses, it is easy to visualize the process as it would occur; while in other parts of the book the reader is made aware of the possible dangers of interpretation, for example, when the infectivity of viral nucleic acid is considered. Some excellent photographs, diagrams and tables help to convey the data.

The later chapters are concerned with the various modes of virus-cell interaction, and while many facts are described and many references provided for further exploration if desired, the impact, so much in evidence in the earlier section on virus structure, seems to be less. Perhaps this is because some basic concepts of virus infection are not covered adequately—for example, the single-step growth experiment which in 1939 provided the basis for the development of quantitative virology.

Further, there is very little discussion of the genetics of viruses, an omission which is deliberate and explained on the grounds that other books and review articles have covered this topic in detail. In the past three decades, however, studies on viruses have made a considerable contribution to an understanding of biological processes, particularly with regard to the nature and expression of the genetic code. The relevant experiments were possible because of a combination of approaches, that is, details of the virus structure from a physico-chemical viewpoint and of the biology of infection, both molecular and genetic aspects. Accordingly, in an introductory but nevertheless advanced book of this kind, I feel that it would have been advantageous to develop these themes together, even if this necessitated some increase in length.

There is a useful series of questions for each chapter at the end of the book. I recommend the book, particularly for those who require a predominantly experimental introduction to viruses. D. H. Roscoe

IMMUNOLOGICAL DISEASE

Autoimmunization and the Autoimmune Hemolytic Anemias

By Bernard Pirofsky. Pp. xiii + 537. (Williams and Wilkins: Baltimore. Distributed in the UK by Livingstone: Edinburgh, 1969.) 180*s*.

In this book Professor Pirofsky develops his thesis that autoimmune haemolytic anaemias are but one manifestation of a diffuse immunological systemic disease either genetically determined or caused by vertical transmission of virus infection in an immuno-deficient individual. This theme runs throughout the book, though technically it is divided into two parts, the first dealing predominantly with the clinical and haematological aspects of acquired haemolytic anaemias, and the second reviewing the theoretical and immuno-haematological evidence of a positive antiglobulin test and its relation to auto-immunization.

In the excellent historical review, the acquired haemolytic anaemias are examined in relation to the concept of an antibody produced by an individual and specifically directed against his own unmodified erythrocytes. On this criterion many of the antiglobulin positive immunohaemolytic anaemias can be shown to have antigens modified by drugs or cross-reacting antibodies stimulated by various environmental factors such as disease states, drugs and viruses. There is an extensive analysis of the author's series of 234 patients with warm acting erythrocyte antibodies studied from 1958 to 1966. The most striking features of the series are the remarkably high incidence of autoimmune haemolytic anaemia secondary to the leukaemias and the subsequent development of lymphomas in patients initially diagnosed as idiopathic haemolytic anaemia. Because of these features, the possibility exists that the term idiopathic is illusory and a longer follow up is necessary to define the true pattern of the disease.

The chief diagnostic criterion, a positive direct antiglobulin test, was found to be negative initially in thirty cases in the series and only repeated investigations in combination with enzyme tests enabled a firm diagnosis to be made. The therapy of all aspects of the disease, both primary and secondary, is well covered.

The second part of the book reviews the theoretical and immunohaematological implication of the clinical viewpoint and tries to define the terms so that the subject is not bedevilled by the semantics which have previously caused confusion owing to the extended ways in which the term autoimmune has been used. The final form of the book is derived from a preliminary text dominated by a "stream of consciousness" literary style: there are chapters on the self recognition phenomenon and the thirteen mechanisms leading to the state of autoimmunization are outlined in chapter thirteen and elaborated in the two subsequent ones.

One is conscious, in this book, of flights of imagination many of which are difficult to follow, and the repetition of many of the arguments does not add to its clarity. The whole work could be improved by a severe pruning of repetitive material. It is, however, undeniably useful as a complete compilation of every aspect of acquired and autoimmune haemolytic anaemias together with all the drugs and diseases which have been associated with increased haemolysis. M. M. Pickles

FIELD GUIDE FOR THE ARMCHAIR

Flowers of Europe

A Field Guide. By Oleg Polunin. Pp. 662 + 192 pages of illustrations in colour. (Oxford University Press: London and New York, June 1969.) 84*s*.

One botanizing season has already passed in Europe since the publication of this book, so its value as a field guide to European plants has been experienced by those who have used it. There is no doubt that it filled a gap in European botanical literature, for here, at a modest price for its size and content, is a single volume describing and illustrating a good selection of phanerogams. On the whole, it can hardly be recommended to professional taxonomists, because out of a figure far exceeding 15,000 species of seed-bearing plants natively growing in Europe or naturalized there, this work deals with only about 2,800 species. It is intended for, and best suited to, the ordinary traveller who wants to name and know something about the plants he stumbles across while he is on holiday.

The choice of included species must have been difficult and the criteria used in making it have been abundance, attractiveness, individuality and fame. About 1,900 plants are given full treatments—their principal diagnostic characters, a list of the countries in which they have been found, and their uses in healing, as poisons, dyes or food plants. As this is primarily a book for identification, keys to families and genera are given, and species in each genus are grouped under key-like headings to make identification simpler. The author in his preface stresses the importance to the layman of having colour photographs, and includes in his book more than 1,000 colour plates. There are also about 300 line drawings of plants. Throughout the book botanical terminology is kept at a minimum (but, we are told, not at the expense of accuracy), and those terms that have, inevitably, to be used are defined in a 15-page illustrated glossary. There is a very useful bibliography, and a list of popular names in English, French, German and Italian. The splitting of the contents of the book into two indexes, one English and the other Latin, is a tedious and frustrating practice for which I know no justification.

The descriptions of individual species are concise and consist of the principal diagnostic characters by which the plants may be identified: the mass of detail often discovered in a standard work is eliminated. Occasionally, there is an attempt to give the reader a thumb-nail impression of the plant first, before proceeding to the details. There is some inevitable inconsistency in the success of this, because some plants are more conducive to the treatment than others, but on the whole it is well done. Although the book is called a "Field Guide", this is not to be taken too seriously. Only the most stalwart would brave more than a few hundred yards with it in his rucksack (it weighs more than 3 pounds), and the information on uses of plants, although short, is an incidental inclusion that one can forgo in the field. It is an empty boast that the colour plates show the "nuances of posture, colour, form, and habitat" of the plants. There are some very fine photographs of which the one of *Gentiana lutea* on the dust-jacket showing the whole plant set against a mountainous background is probably the best; but many have unreal colours, a few are actually out of focus, a high proportion show inflorescences without leaves, and only about 10 per cent (a liberal estimate) show the plants growing in a recognizable habitat. The line drawings are excellent.

For those who do not need or cannot afford to buy a comprehensive work such as the *Flora Europaea* (which is as yet incomplete), the present work is a most commendable substitute. A. R. PERRY

DIVERSITY OF FLOWERING

The Induction of Flowering

Some Case Histories. Edited by L. T. Evans. Pp. 488. (Macmillan: Melbourne and London, July 1969.) A$20.

ONE of the dominant themes of contemporary molecular biology and biochemistry is the essential unity of living matter, so that we are understandably more impressed by the similarities in cell structure and metabolism of widely different organisms than by their differences, and we feel justified in extrapolating from unicellular algae to beans and apple trees, or even "from peas to people". When we come to consider whole organisms, however, they manifestly are different, both in structure and in physiology, and it becomes more difficult to extract general principles from a mass of particular detail. Since the importance of day length and winter chilling (vernalization) in controlling flowering in many plant species was first clearly established about 50 years ago, an impressive body of observational data has been accumulated for a large number of species. From these detailed facts certain generalizations have emerged, such as the probable universal involvement of phytochrome in photoperiodic control, which constitutes an excellent example of the inductive method in science. Success of this sort encourages us to seek other unifying concepts, such as a universal mechanism of flowering, involving a single "flower hormone".

This book, which comprises a series of case-histories of twenty species of plants which have been extensively used in studies on the physiology of flowering, is a salutary antidote against a too-ready assumption that there is a single, universal mechanism of flowering control in all higher plants. Twenty authors have each contributed a chapter which brings together and summarizes all the available information on the physiology of flowering of a selected species.

The aims of this study are stated to be "to expose the diversity of flowering behaviour rather than to neglect it or confine it within a few generalizations", and there is little doubt that this aim is achieved. One might have hoped, however, for some new insight into the flowering processes through the bringing together of all the information for single species to form an integrated and consistent picture. But in these studies each chapter remains essentially a separate case-history in which the facts are presented with little attempt at interpretation, although there is a valuable final chapter by the editor, Dr L. T. Evans, in which he critically examines some of the major concepts in the physiology of flowering.

The chosen species were selected primarily on the grounds that they had been extensively used for experimental studies and only a few, such as chrysanthemum, strawberry, pea, tomato and hemp, are of economic importance. The book is likely to be of value primarily to specialist research workers in the field of flowering physiology, and will provide a valuable reference work, as I have already found for my own work. It will also be useful to those responsible for the teaching of advance courses in plant physiology and to postgraduate students working in this field. P. F. WAREING

PROPERTIES OF SEAWATER

Marine Chemistry

The Structure of Water and the Chemistry of the Hydrosphere. By R. A. Horne. Pp. xxii + 568. (Wiley (Interscience): New York and London, November 1969.) 190*s*.

IN spite of its obvious and rapidly growing importance, the subject of marine chemistry has been largely neglected by the authors of textbooks. This is a complete contrast to most other branches of marine science, such as physical oceanography and marine geology, for which many excellent texts are available. This book, by R. A. Horne, is therefore welcome, particularly because it deals with the subject from a physico-chemical standpoint, unlike earlier works which have been largely descriptive. The author intends it to be used as general reading by marine scientists, as an advanced text by graduate students, and also as a source of available tabulated data of the properties of seawater.

The book is divided into four parts which it is convenient to discuss separately. Part one deals with the structure of water and the physical chemistry of electrolyte solutions with particular reference to seawater. As befits the author's distinguished research career in this field, this is the best section in the book. His treatment of this difficult and controversial subject is extremely lucid and could be read with profit by all marine chemists.

In comparison with the overall excellence of part one, the remaining three parts which deal chiefly with processes occurring in the sea are poor and ill-balanced except where they abut onto physical chemistry. I was left with the feeling that the author has been very selective in his reading and that he is unaware of much of the recent work on these subjects. It is unfortunate that there is not even a short account of the oceanic water circulation pattern, or of the processes causing mixing, because these to a very large extent control, or modify, the distribution of the chemical parameters in the sea.

Part two is devoted to a discussion of the chemical composition of seawater and the factors influencing it. The dissolved gases and chemical species in seawater are competently discussed (although it seems extraordinary to state (page 18) that the Ca/Cl‰ ratio is quite constant, when it has been known since 1884 that it is not, and to accept uncritically the controversial variation of the Sr/Cl‰ ratio). Some extremely important subjects, however, are treated in an extremely skimpy fashion, for example, the micro-nutrient elements—nitrogen and phosphorus—are dismissed in a mere 130 lines. Some other sections are rather out of date, and tend to be hotchpotches of rather ill-digested material, some of which has little relevance to the subject. This is particularly true of the chapter on the biochemistry of the ocean—thus, I would question the need for Fig. 9.2, showing the α-helix of the milk protein molecule, and Table 9.6, giving the amino-acid compositions of some proteins, not one of which is marine in origin.

The third part is concerned with the chemistry of the marine interfaces, and this includes a section on marine sediments. The latter consists of a number of isolated topics, evidently chosen from the literature in an unselective way, without any attempt to discriminate between important and trivial aspects of marine sedimentary geochemistry. This is revealed particularly by the author's choice of tables. In part four, a number of selected topics are discussed. These include marine corrosion, recovery of raw materials from the sea, and the origin of life in the sea. The book concludes with a very useful 60 page appendix containing tables of physical and physico-chemical properties of seawater.

The book is well printed and bound. It is marred, however, by an excessive number of printing errors, a few examples of which are: the temperature of −607° C in Table 1.1; the reference to a platform (platinum) indicator electrode (page 133); several errors in the radioactive decay series (pages 293–294). About half of the book is composed of tables and figures, several of the latter being of unnecessary crudity, for example, 1.1, 1.21, which are of primary school level. Although most of the writing is clear and unexceptionable, I found the author's numerous philosophical digressions extremely irritating.

In spite of my criticisms, however, this is a book which, because of its physico-chemical approach, should be read by every marine chemist. Unfortunately, it is unlikely to be of much value to marine biologists because the treatment of biochemical processes in the sea is brief and superficial and, most surprisingly, primary productivity does not seem to be mentioned directly at all.

J. P. RILEY

IONIZED ATMOSPHERE

Introduction to Ionospheric Physics

By Henry Rishbeth and Owen K. Garriott. (International Geophysics Series, Vol. 14.) Pp. x + 331. (Academic Press: New York and London, August 1969.) 149*s*.

THE ionosphere, that vast natural plasma which envelopes the Earth, is the concern of workers in a wide range of scientific disciplines. Over the years, contributions have come from astronomers, physicists, chemists, radio engineers, geomagneticians and others, and a comprehensive account of all aspects of current knowledge of the ionosphere would indeed call for a very substantial volume. The authors of this book are well aware of the problems inherent in writing only about selected topics, and in their preface they set out quite clearly what the book is, and is not, intended to do. The stated purpose is "to discuss the physical processes at work in the ionosphere and to relate them to the observed facts of ionospheric behaviour, without too much detail", and the authors add that the volume is "intended to be useful to physicists, especially graduate students, possessing no great knowledge of the upper atmosphere". A reading of the text confirms that these objectives have been achieved in full.

The subject matter has been grouped into eight principal sections—the neutral atmosphere; ionospheric measurements; photochemical processes; transport processes; morphology; some ionospheric phenomena; geomagnetism and the ionosphere; and storms and their ionospheric effects. Useful tables give, at a glance, orders of magnitude of essential numerical parameters or summary statements on such things as electron production and loss processes, photochemical reactions and ionospheric storm phenomena. A carefully chosen representative bibliography of some 700 documented references is also included. The style and general presentation of the material leave little to be desired and the authors have used wise discretion in deciding the detail with which any particular topic should be treated. In some cases, discussion has been limited because of the uncertain character of current knowledge; in other cases, a subject has not been dealt with in detail because to do so would have upset the general balance of the book. The overall result is a really excellent, authoritative introduction to the subject.

Readers will note that the senior author, Dr Henry Rishbeth, is a member of the staff at the Radio and Space Research Station, Slough, and that his co-author, Dr Owen Garriott, is at the Manned Spacecraft Center, Houston. It may not be generally known that Garriott is, in fact, currently training to be an astronaut. Presently, he will thus have the unique distinction of being the first ionospheric worker to make a first hand acquaintance with his subject.

Bearing in mind the objectives which the authors set themselves, this book can be recommended without reservation.

W. J. G. BEYNON

LAWS FOR SYSTEMS

Thermodynamique et Physique Statistique, Premier Cycle

By Bernard Jancovici. Pp. xii + 184. (Ediscience: Paris, 1969.) n.p.

THIS book is designed to provide a simple introduction to thermodynamics and statistical physics. It proceeds from a standpoint of microphysics, and the principles of thermodynamics are presented as consequences of mechanical laws for systems composed of very large numbers of particles. By presenting thermodynamics in this way, the author deliberately avoids a number of sophistries involved in the classical expositions of this subject. In particular, he eliminates the problem of interpreting the entropy concept in terms of purely macroscopic operations.

The book opens with a provisional definition of temperature, based on elementary kinetic theory. This definition is later supplanted by a more generally applicable one, but its introduction enables the author to provide a description of the macroscopic states of matter (phase diagram, van der Waals's equation and the like) at an early stage of the book.

In chapter two, the internal energy of a system is defined in microscopic mechanistic terms. This definition leads directly to the first law. In the following chapter, the entropy of a system is defined as the logarithm of the number of quantum states in an appropriate energy shell; and the temperature is defined as the reciprocal of the partial derivative of entropy with respect to internal energy. These definitions are then used to formulate the Zeroth, second and third laws of thermodynamics. Chapter four is devoted to various applications, at the macroscopic level, of the laws formulated in earlier chapters.

Thus, in the first four chapters, microscopic principles are used for the purposes of defining the thermodynamical variables and formulating the laws of thermodynamics. On the other hand, the fifth (and final) chapter provides an introduction to statistical mechanics proper. This chapter opens with a simplified derivation of Boltzmann's distribution law for a system (possibly macroscopic) in diathermic contact with a thermal reservoir. This law is then applied to relate a number of macroscopic phenomena to the atomic constitutions of the relevant systems (for example, paramagnetism of solids, specific heats of crystals).

The exposition is very clear throughout. I consider that this book should serve as a useful introduction both to thermodynamics and to statistical physics.

G. L. SEWELL

DEFORMATION OF SOLIDS

Elasticity, Fracture and Flow with Engineering and Geological Applications

By J. C. Jaeger. (Methuen's Monographs on Physical Subjects.) Pp. viii + 268. (Methuen: London, November 1969.) 30*s*.

PROFESSOR JAEGER's monograph is a third edition which incorporates without significant change the whole of the first (1956) edition under the same title. It also includes an extended version of the material on rock mechanics that was added in the second (1962) edition, and a substantial new section on applications of the ideas developed earlier to a study of the fundamentals of structural geology.

The reader is guided step by step from the classical account of deformation and flow with which engineering students will be familiar, including finite strains and yield criteria, through a discussion of such complications as plastic flow, firmo-viscosity, brittle fracture and earthquake waves, until he can appreciate finally the more subtle refinements that the geologist must make allowance for. These include stress patterns near boreholes, tunnels and cracks, the dependence of elastic moduli on strain, strain rate and temperature (attributed largely to the presence of pores in rocks), ductility and strength, planes of weakness, liquid flow through porous media, the difference between laboratory tests on sound specimens and field tests on rock formations with breaks and other imperfections, and progressive finite deformation over geological periods of time (to be explored with veins, fossils and inhomogeneities as the only visible indicators). Wherever possible, both theoretical and observational considerations are brought together on each topic.

The argument is developed throughout with full mathematical detail, a high standard of accuracy and freedom from misprints, always in a clear, easily readable style. A glossary of the chief symbols used and separate author and subject indexes are appended. References to original papers and other works are included in the text.

This book can be recommended as giving a sound and clear account of deformation and flow in theory and in practice, admirably suitable for the geologist and the engineer and worthy of the attention of students of other disciplines seeking a balanced introduction to the general deformation of solids.

J. G. Oldroyd

SPECTRAL ANALYSIS

Rotational Structure in the Spectra of Diatomic Molecules

By István Kovács. Pp. 320. (Hilger: London, November 1969.) 104*s*.

The name of Professor Kovács is well known to spectroscopists who analyse the rotational fine structure of the electronic spectra of diatomic molecules. In this book, all his own work on multiplet formulae, line intensities and on spectroscopic perturbations is included, together with similar equations derived by other workers in the most fundamental area of spectroscopy.

The first chapter deals with the solution of the wave equation for a diatomic molecule and includes many of the small interactions which are frequently neglected in approximate treatments. The rest of the book consists of applications of perturbation calculations to various types of interaction for all the commonly observed species of spectroscopic state and for many which are rarely seen or as yet unknown. Multiplet term formulae are derived for states with all multiplicities from singlet to septet. Each formula is tested by application to observed spectra and in most cases the agreement with theory is impressive. The intensity distribution formulae, which are presented very fully, should be the most useful part of the book. In particular, this section will be welcomed by astrophysicists, who are increasingly interested in the spectra of diatomic molecules.

A regrettable omission in a book published in 1969 is any account of nuclear hyperfine structure, which can alter the appearance of rotational structure and lead to incorrect analysis as in LaO. Again, a difficulty in this type of work is that many of the interactions are introduced as configuration interaction with other states. Such interactions are limited to one or two states, whereas, in reality, a whole spectrum of energy levels will interact. To include more than a few interacting states would make formulae which are already formidable into something quite unmanageable, but it does mean that if the formulae are ever found to fail an excuse in terms of configuration interaction can usually be made.

W. G. Richards

Obituaries

Professor E. H. F. Baldwin

Ernest Baldwin, who died suddenly on December 7, 1969, will be remembered not only as one of the chief protagonists of comparative biochemistry but for his outstanding contributions to teaching. Educated at the Crypt Grammar School, Gloucester, he went up to St John's College, Cambridge, as an exhibitioner in 1928. He took a first in both parts of the Natural Sciences Tripos, including Part II Biochemistry. In 1936 he became a research fellow of his college and in 1943 a lecturer on the staff of the Biochemical Department under Sir Frederick Gowland Hopkins. Greatly influenced by Hopkins's wide ranging approach to biochemistry, Baldwin applied his zoological knowledge to extending the comparative aspects of the subject and in particular nitrogen metabolism. One of the earliest results of this was his little book *Comparative Biochemistry* (1937), which is still recognized as a classic introduction to the subject.

During this time Baldwin was also acquiring a wide reputation as a teacher. His sense of the modern and interesting and his quietly dramatic presentation appealed strongly to students, and the theatre was always full. During the war years much of the teaching burden in biochemistry fell on him, so that he had to cover a wide field. One product of this was *Dynamic Aspects of Biochemistry* (1947), a book that had a worldwide impact on the teaching of the subject. The presentation, based on his inspiring lectures at Cambridge, was entirely new and it was received with unusual warmth. Its sales have by now exceeded 80,000 copies in five editions and five reprints; and it has been translated into seven languages (German, Italian, Spanish, Russian, Serbo-Croat, Japanese and Malay), thus winning acclaim for British biochemical teaching. A considerable part of its success lay in its undoubted literary merit, and indeed it gained for Baldwin the European Cortina-Ulisse prize in 1952.

In 1950 Baldwin was called to the chair of biochemistry at University College, London. His appointment belied the received idea that university teachers are elevated to chairs solely on the basis of their research contributions, for there is no doubt that Baldwin's great merits as a teacher weighed heavily in his selection. University College, under F. G. Young, had taken the first steps towards the establishment of a BSc special degree in biochemistry. It needed a professor with a high reputation as a teacher to carry through the negotiations with the university to a satisfactory conclusion and to establish the new course on a sound footing.

Baldwin remained at UCL for the next twenty years. During that time, in spite of frequent ill-health, he added much to our knowledge of the comparative biochemistry of nitrogen metabolism and the relation between ureotelic metabolism and water shortage, building up an internationally known school of research workers in such subjects. Curiously, this endeavour was always valued more highly in the United States and on the Continent than in Britain. In it Baldwin was ahead of his more conservative contemporaries, and it is only of very recent years that the movement to cross boundaries has made much progress here. Baldwin's influence at UCL was particularly important, for he saw biochemistry as a "biological" subject and his views were thus a valuable counter to the prevailing London conception of biochemistry as a branch of chemistry.

Bearded and amiable, quizzical and fastidious, the figure of Ernest Baldwin will be sadly missed, not only in the neighbourhood of Gower Street but also in his old haunts at Cambridge. It was from St John's that he went forth for his early work with friends at the French marine biological stations such as Roscoff and Tamaris; and the Biochemical Institute in Tennis Court Road saw some of his most notable achievements. There he was a particularly active organizer of the International Congress of Biochemistry in 1949, editing for it in collaboration the memorial volume *Hopkins and Biochemistry*. Baldwin was indeed a most worthy disciple of Frederick Gowland Hopkins. A good friend, a kindly director, a fine scientist and a gifted writer has been lost at too early an age to all of us.

Correspondence

Goldfinger no Longer

SIR,—You say that "it is arguable that a research council should divest itself of supporting the routine data collection that comprises much of the work of the institutions. This is not research and only occasionally aids research" (*Nature*, **225**, 2; 1970). I doubt whether these propositions are arguable in respect of any major field of science but they are quite untenable in regard to environmental research.

Penetrating research on the natural environment is impossible without programmes of field data collection. In answer to your suggestion that work of this kind should not be done in research institutions, I say that it would be disastrous if it were to be done anywhere else.

If your propositions were to be accepted, it would mean that the NERC would be able to support research on the input components of the natural system (in terms of physiology and biochemistry, for example) but would find it difficult to support analyses of the outputs in terms of field observations; or, at least, you would not support those field studies which deal with extensive time-series or large areas. The point which you have missed is that some kinds of research depend on the availability of collections of observations in the field, often on a scale which can be achieved only by establishing a systematic programme of sampling. The resolution, accuracy and scale of such observations must be determined by the objectives of the research programme. Thus they are as integral to research as a physiologist's laboratory equipment and measurements, for example.

Environmental research cannot exist without the description, analysis and interpretation of events and processes in nature. This is becoming even more essential with the increasing threat of pollution. The detection and measurement of the effects of pollution in the field will always be difficult, and often impossible, without a thorough understanding of the base-lines of natural variation. It would be extremely dangerous to predict the consequences of pollution, or to devise precautions against it, without a sound knowledge of natural ecosystems. Any attempt to monitor pollutants will be pointless unless we also monitor the communities and ecosystems. Essential laboratory studies of topics such as toxicity will be wasted unless they can be related to ecological field studies. Thus fundamental research on natural variations lies at the core of the investigation of pollution as it does of almost every branch of environmental science. The scale of natural variation is such that it demands the analysis of field observations taken frequently over a very long period of years and, often, from a very wide area.

In the past, much so-called ecology has dealt with single species, limited regions or restricted periods, rather than with communities and ecosystems. Of the many reasons for this, the most important are the severe practical as well as intellectual difficulties in analysing nature; especially, perhaps, in studies of the oceans. However, the revolution in electronics is now beginning to remove these impediments by providing the sensors with which to make the observations, the data loggers on which to record them and the computers with which to analyse them.

My excuse for making so many self-evident points is that your propositions, if unchallenged, would deny environmental science the principal opportunity for advance in this last third of the twentieth century. This is the establishment of research programmes based on the systematic collection and analysis of field data—linked, of course, to the essential experimental and theoretical studies.

In the environmental sciences, at least, applied science is no more than fundamental research on those things which matter to society. Any attempt to define the limits or to isolate either kind of research is bad for science and wasteful for society. I believe that your propositions are both.

Yours faithfully,

R. S. GLOVER

Scottish Marine Biological Association,
Oceanographic Laboratory,
78 Craighall Road,
Edinburgh EH6 4RQ.

University News

Dr Francis J. Smith has been appointed director of the Computer Laboratory at the **Queen's University of Belfast.**

Dr J. N. Hawthorne, University of Birmingham, has been appointed professor of biochemistry in the **University of Calgary.**

Air Marshal Sir Kenneth Porter, Royal Air Force Maintenance Command, has been appointed director of technical education projects at **University College, Cardiff.**

Professor Maurice D. Kilbridge has been appointed dean of the **Harvard Graduate School of Design.**

Dr James F. Tait, Worcester Foundation for Experimental Biology, has been appointed to the Joel Chair of Physics as Applied to Medicine tenable at the **Middlesex Hospital Medical School.** The title of Professor of Urology has been conferred on **Mr J. P. Blandy** in respect of his post at the **London Hospital Medical College.**

Professor N. Millott, Bedford College, has been appointed director of the newly instituted University Marine Biological Station, Millport, and professor of zoology in the **University of London.**

The **University of Nottingham** has appointed three special professors in the Department of Physiology and Environmental Studies, School of Agriculture: **Dr L. E. Mount,** ARC, Babraham (Environmental Physiology); **Mr K. J. Hill,** Unilever Research Laboratory (Animal Physiology); **Dr W. R. Butt,** United Birmingham Hospitals (Clinical Endocrinology).

Dr Hans Meidner has been appointed to the newly established chair of plant biology in the **University of Stirling.**

Professor Charles L. Miller has been appointed associate dean of the School of Engineering, **Massachusetts Institute of Technology,** and **Professor Peter S. Eagleson** has been named head of the Department of Civil Engineering within the school.

Appointments

Professor Herwig F. Schopper has been appointed leader of the Nuclear Physics Division at **CERN.**

Dr Theresa Clay has been appointed deputy keeper in the Department of Entomology, **British Museum (Natural History).**

Mr G. R. Walter de Silva of Ceylon has been appointed by the **International Atomic Energy Agency** to be regional officer for Asia and the Far East.

Dr J. R. F. Martineau, formerly secretary of the Defence Research Board, has been appointed to take charge of the International Relations Office of the **National Research Council of Canada.**

Dr P. S. Wellington has been appointed director of the **National Institute of Agricultural Botany** in succession to **Mr F. R. Horne.**

Dr Elliot S. Pierce has been appointed director of the Division of Nuclear Education and Training, **US Atomic Energy Commission,** in succession to **Dr Russell S. Poor.**

The **Ministry of Technology** has appointed four new regional directors, following reorganization of its regional offices: **Mr Ian Gray** (director for Wales); **Mr L. Ian Macbeth** (director for the South Western region); **Mr Ronald Wood** (director for the Northern region); **Mr Ernest Atherton** (director for the North Western region).

Mr Oran W. Nicks has been appointed acting associate administrator for advanced research and technology of the **National Aeronautics and Space Administration,** in succession to Mr Bruce T. Lundin.

Professor Keith Legg, Loughborough University of Technology, has been appointed consultant adviser to the Centre for Educational Research and Innovation of the **Organization for Economic Cooperation and Development.**

Announcements

The **Messel Medal** of the Society of Chemical Industry has been awarded to **Sir Eric Rideal.**

Dr Jay W. Forrester, Massachusetts Institute of Technology, has been awarded the **Valdemar Poulsen Gold Medal of the Danish Academy of Sciences** for his outstanding contribution to the development of the digital computer.

5,000 Swiss francs will be awarded by the **International Health Foundation** for the best paper submitted to the Foundation on any aspect of osteoporosis. Papers, which should not exceed 2,500 words and should contain original ideas, must be submitted before May 1. Further details can be obtained from the International Health Foundation, 14 rue de Hollande, 1204 Geneva, Switzerland.

The trustees of the **Lady Tata Memorial Trust** invite applications for fellowships and scholarships for research on any aspect of malignant disease which is relevant to the problems of leukaemia. Further details can be obtained from the secretary of the (European) Scientific Advisory Committee, Lady Tata Memorial Trust, Chester Beatty Research Institute, Fulham Road, London SW3.

The **Institute of Contemporary Arts** invites contributions to an exhibition of Unlikely Photography, which will consist of three sections: photographs of things that cannot be illustrated; photographic misrepresentations; three-dimensional photography. Further details can be obtained from the Institute of Contemporary Arts, Nash House, 12 Carlton House Terrace, London SW1.

A bequest by the late Mrs K. E. Maltwood has enabled the **Royal Society of Arts** to establish a fund to assist projects of archaeological research in Somerset which are of outstanding national importance. The society now invites applications for grants from the fund for work to be carried out in 1970. Further details can be obtained from J. S. Skidmore, assistant secretary, Royal Society of Arts, John Adam Street, Adelphi, London WC2.

International Meetings

March 19, **Automation in Production, Sampling and Testing of Silicate Materials,** London (J. M. Rowell, Society of Chemical Industry, 14 Belgrave Square, London SW1).

March 22–25, **American Association of Physical Anthropologists,** Washington, DC (Dr J. L. Angel, Division of Anthropology, Smithsonian Institution, US National Museum, Washington, DC 20560, USA).

Sabbatical Itinerants

In the hope of providing some practical assistance in the good cause of mobility between laboratories, *Nature* advertises the needs for housing of families about to take up periods of sabbatical leave. To begin with, no charge will be made for advertisements like this. It is hoped that a period of experiment will show what form these advertisements could most usefully take and whether they are effective.

Wanted: From July 1970 to April 1971. Apartment or house near University of Copenhagen for chemist, wife and two small children. Please contact Dr N. W. Alcock, School of Molecular Sciences, University of Warwick, Coventry, Warwickshire CV4 7AL.

Wanted: 4-bedroom furnished house, preferably centrally heated, convenient to Hammersmith Hospital, for 1 year from July 20, 1970. Can offer similar accommodation in Syracuse, New York. Please contact Professor D. A. Nelson, Department of Clinical Pathology, Upstate Medical Center, Syracuse, New York 13210.

Wanted: For 3 months from April 1, 1970, furnished 3-bedroomed house in London. Rent up to £35–£40 per week, or exchange for furnished 3-bedroomed house in beautiful suburb, 5 miles from Rutgers University, 15 miles from Princeton University and 35 miles from New York City. Please contact Dr Bernard Beer, 6 Renfro Road, Somerset, New Jersey 08873.

Wanted: 4-bedroom house, preferably centrally heated, in or near Oxford, for 1 year starting September 1, 1970. Please contact Dr W. M. Thurlbeck, 602 Victoria Avenue, Westmount 217, Montreal, Quebec, Canada.

Vacant: 5-bedroom house in best part of Montreal, 10 minutes from McGill University and Université de Montreal, for 12–14 months starting summer 1970. Please contact Dr W. M. Thurlbeck, 602 Victoria Avenue, Westmount 217, Montreal, Quebec, Canada.

Vacant: From July 1970 to April 1971, comfortable terrace house, central heating, 3 bedrooms. Leamington Spa, convenient for University of Warwick. Please contact Dr N. W. Alcock, School of Molecular Sciences, University of Warwick, Coventry, Warwickshire CV4 7AL.

British Diary

Monday, February 9

A Volunteer at Masada (5.30 p.m.) Miss Katherine Blair, Royal Institution, at 21 Albemarle Street, London W1.

Colour Television Receiver Design and Maintenance (6 p.m.) Mr G. D. Barnes, Institution of Electronic and Radio Engineers; and the Institution of Electrical Engineers, at the University of Strathclyde, Glasgow.

Polymers in the Year 2000 (7.30 p.m.) Professor C. E. H. Bawn, CBE, FRS, Institution of the Rubber Industry, at the Donnan Laboratories, The University, Liverpool.

Techniques of Mask-Making (2.30 p.m. colloquium) Institution of Electrical Engineers, at Savoy Place, London WC2.

Tuesday, February 10

Dynamic Information Displays (6.30 p.m.) Mr D. W. G. Byatt, Institution of Electronic and Radio Engineers, at the University of Colchester, Essex.

Future Trends in Analytical Chemistry (6.30 p.m.) Dr J. B. Headridge, Society for Analytical Chemistry; and the Royal Institute of Chemistry, in the School of Chemistry, Newcastle University.

Making the Best of a Bad Job—What Engineering Is (5.30 p.m.) Professor E. R. Laithwaite, Royal Institution, at 21 Albemarle Street, London W1. (Lecture for Sixth Form Pupils from Schools in London and Home Counties. To be repeated on February 11, 17 and 18.)

Mathematician's Utopia (1.20 p.m.) Mr M. J. Brown, University of London, in the Botany Theatre, University College London, Gower Street, London WC1.

Primers for Metal (forum) Oil and Colour Chemists' Association, at the Griffin Hotel, Boar Lane, Leeds 1.

Recent Work on Dithizone and Its Selenium Analogue (5.15 p.m.) Professor H. M. N. H. Irving, Society for Analytical Chemistry; and Leeds University Union Chemical Society, in the Chemistry Department, University of Leeds.

Scientific Knowledge and the Press (7.30 for 8 p.m.) John Davy and Professor J. M. Ziman, British Society for Social Responsibility in Science, at the Blackhorse, Rathbone Place, W1.

The Ageing Process in the Human Brain (5.30 p.m.) Dr J. A. N. Corsellis, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1.

The Tunnelling of Shipworms, Mr P. A. Board; **Cell Specialization and Chemosensitivity in Fish Skin,** Dr Mary Whitear; **After the Torrey Canyon** (film) (5 p.m.) Zoological Society of London, at the Zoological Gardens, Regent's Park, London NW1.

Wednesday, February 11

Analytical Cosmochemistry (or Migrants from Outer Space Enter the Chemical Laboratory) (6.30 p.m.) Dr A. A. Smales, Society for Analytical Chemistry, in the Mechanical Engineering Department, Imperial College, London SW7.

Annual General Meeting; The Modern Manual Instrument; and **Exhibition** (2 p.m.) Photoelectric Spectrometry Group, at the School of Pharmacy, Brunswick Square, London WC1.

Computer Applications in Shipping (5.30 p.m.) Mr H. Phillips, Institution of Electrical Engineers; the Institute of Measurement and Control; and the Automatic Control Group of the I.Mech.E., at Savoy Place, London WC2.

Gnotobiotic Animals (Germ and Pathogen-Free Animals) (6.15 p.m.) Professor A. O. Betts, Society of Chemical Industry, Food Group, at 14 Belgrave Square, London SW1.

Nuclear Power Up-Dated (7 p.m.) Dr H. Kronberger, FRS, Institution of Electrical Engineers, at Culham Laboratory, Harwell.

Plasticizers—Compatibility and Performance (7.30 p.m.) Mr J. L. Fowler, Institution of the Rubber Industry, at the Polygon Hotel, Southampton.

Problems Arising from the Water-Cooling of Engine Components (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

Telecommunication Switching—a Review of Technological Progress (5.30 p.m.) Mr J. R. Pollard, Institution of Electrical Engineers, at Savoy Place, London WC2.

The Communication of Scientific Information through Experimental Demonstrations (1 p.m.) Mr F. C. Brown, Royal Institution, History of Science Discussion Group, at 21 Albemarle Street, London W1.

The Functions of the Ministry of Technology in the Field of Industry (7.15 p.m.) Mr K. W. Doble, Plastics Institute, at The University of Wales Institute of Science and Technology, Cathays Park, Cardiff.

Thursday, February 12

Biochemical Aspects of the Control of Energy Production in the Liver of the Normal Rat and After Physical Injury (5 p.m.) Mr C. J. Threlfall, University of London, at the Middlesex Hospital Medical School, Mortimer Street, London W1.

Botany or Molecular Phytobiology? (8 p.m.) Professor J. Friend, in the University Lecture Theatre, University of Hull.

Fluorescence Spectroscopy (2 p.m.) Society for Analytical Chemistry, in the Special Lecture Theatre of Liverpool Regional College of Technology, Byrom Street, Liverpool.

Mechanization of the Assembly Process in Small and Medium Batch Production (4.30 p.m.) Mr J. R. Ashley, Royal Society, at 6 Carlton House Terrace, London SW1.

New Resin Systems for Use in Coil-Coating Applications (6.30 p.m.) Mr L. A. Tysall, Oil and Colour Chemists' Association, in the New Engineering Block, University College London, Gower Street, London WC1.

Non-Empirical, Synthetic Truths in Mathematics (5.30 p.m.) Professor Paul Lorenzen, University of London, at the London School of Economics and Political Science, Houghton Street, London WC2.

Performance Requirements and Test Methods for High-Voltage AC Motor Insulation (5.30 p.m.) Mr K. K. Schwarz, Institution of Electrical Engineers, at Savoy Place, London WC2.

Photovoltaic and Thermoelectric Conversion—Recent Developments in Materials and Devices (10 a.m. colloquium) Institution of Electrical Engineers, at Savoy Place, London WC2.

The Corrosion of Metals in Aqueous Conditions (7 p.m.) Dr P. T. Gilbert, Liverpool Metallurgical Society, in the Department of Metallurgy and Materials Science, The University, Liverpool 3.

The Effects and Control of Vibration in Machinery (all-day discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

The Engineering Implications of Nucleonic Measurement (6 p.m. discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

The North Sea Continental Shelf Cases (5 p.m.) Mr E. D. Brown, University of London, in the Weldon Theatre, University College London, Gower Street, London WC1.

Vascular Endothelium and Its Relation to Blood-Flow (5.30 p.m.) Dr Helen Payling Wright, University of London, at the Institute of Child Health, 30 Guilford Street, London WC1. (Eleventh of fifteen lectures on "The Scientific Basis of Medicine".)

Friday, February 13

Does the Paint Industry Deserve a Research Association? (6.30 p.m.) Dr G. de Winter Anderson, Oil and Colour Chemists' Association, at the Manchester Literary and Philosophical Society, 36 George Street, Manchester 1.

Non-Empirical, Synthetic Truths in Physics (5.30 p.m.) Professor Paul Lorenzen, University of London, at the London School of Economics and Political Science, Houghton Street, London WC2.

Photochemistry of Paranitrosodimethylaniline (1 p.m.) Dr T. S. Godfrey, Royal Institution, Photochemistry Discussion Group, at 21 Albemarle Street, London W1.

The Ebb and Flow of Atomic Chaos—The Physicist as King Canute (9 p.m.) Professor E. L. Hahn, Royal Institution, at 21 Albemarle Street, London W1.

Monday, February 16

Contention or Polling Techniques for Data-Computer Systems (5.30 p.m. discussion) Institution of Electronic and Radio Engineers, Joint IEE/IERE Computer Group, at the Institution of Electrical Engineers, Savoy Place, London WC2.

Insect Hormones and Insect Control (5 p.m.) Dr K. C. Highnam, Society of Chemical Industry, at 14 Belgrave Square, London SW1.

Recent Advances in Medicine, Surgery and Therapy (6 p.m.) Sir Brian Windeyer, Royal Society of Arts, at John Adam Street, London WC2. (First of three Cantor Lectures. Further lectures on February 23 and March 2.)

The Treatment and Disposal of Industrial Effluent (all-day discussion) Institution of Mechanical Engineers, at 1 Birdcage Walk, London SW1.

HOW TO BUY NATURE

Volumes start in January, April, July and October, but subscriptions may begin with any issue.

The direct postal price per subscription for one copy of NATURE each week is:

12 MONTHS (52 issues and 4 indexes)

Great Britain and Eire.................................**£14.0.0** each
United States of America........(by air freight)............ **$48** each
Canada...........................(by air freight).......... **$52** each
Elsewhere overseas by surface mail....................**£14.0.0** each
(Charge for delivery by air mail on application)
*Shorter periods *pro rata*. (Minimum three months.)

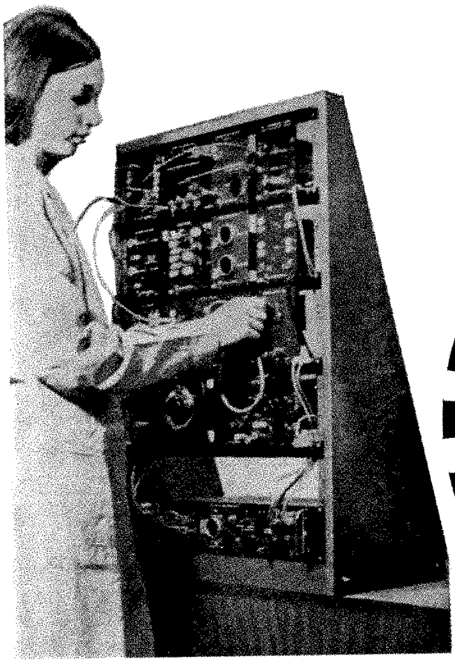
combined behavioural and data acquisition systems

These systems can be operated with equal ease by technicians or research staff. They are research tools for people whose interests are not primarily electrical or electronic. Inexperienced staff can construct a system to reduce qualitative statements into quantitative information.

The apparatus was primarily designed for the Life Sciences but its versatility is such that many applications related to other sciences come to mind viz. complex organic syntheses.



PROGRAMMING, CONTROL AND PRESENTATION SYSTEMS CAN BE DIVIDED INTO THREE CATEGORIES

1. Systems where it is desirable to operate on a single problem for a reasonable period of time and thereafter disperse the equipment throughout individual laboratories for reassembly into smaller self-contained systems for use by separate investigators. The dispersible systems requirements are fully met by the front-patch equipment.

2. Fixed, single-purpose systems in which the requirements are well known and in which extremely infrequent changes are contemplated.

3. A central programming system used by many individuals for different programmes at separate times.

From an enormous list there is a choice of equipment to suit every investigation

Power supplies, print-out and read-out modules, time generators, digital and analogue logic units, statistical generators, interface devices and other interesting units are available. Send for further details now.

APPOINTMENTS VACANT

INSTITUTE OF OPHTHALMOLOGY

(University of London)
Judd Street, London, W.C.1

DEPARTMENT OF PATHOLOGY

TECHNICIAN OR JUNIOR TECHNICIAN required for the routine clinical laboratory. I.M.L.T. Intermediate or equivalent qualifications preferred, but not essential. Good facilities for training for Final examinations.

Please apply in writing, stating age, sex, qualifications, experience and give the names of two referees to The Director at the above address.

(480)

INSTITUTE OF OPHTHALMOLOGY

(University of London)
Judd Street, London, W.C.1

DEPARTMENT OF PATHOLOGY

CHEMICAL PATHOLOGY

SENIOR I/II TECHNICIAN, with experience in automated techniques, required in Chemical Pathology.

The work would entail (a) research on the biochemistry of vascular diseases, and (b) routine investigations in an expanding chemical pathology service to Moorfields Eye Hospital.

Please apply in writing, stating age, sex, qualifications, experience and give the names of two referees, to The Director at the above address.

(481)

UNIVERSITY OF ZAMBIA

Applications are invited for (a) SENIOR LECTURESHIP or (b) LECTURESHIP in PHYSICS. The present research interests are in the fields of defects in solids and applications of radioisotopes ; preference will be given to candidates with experience in one of these fields, or for Senior Lecturer, in geophysics. Experience in teaching elementary Materials Science advantageous. Salary scales (including contract addition for non-Zambians) (a) K5,500 to K6,300 per annum ; (b) K3,500 to K5,300 per annum (K1 = 11s. 8d. sterling). Salary supplemented in range £200 to £250 per annum (sterling) in appropriate case under British Expatriates Supplementation Scheme. Family passages ; various allowances ; biennial overseas leave ; superannuation and medical aid schemes.

Detailed applications (six copies), naming three referees, by March 3, 1970, to Inter-University Council, 90/91 Tottenham Court Road, London, WIP ODT, from whom particulars are available.

(474)

UNIVERSITY OF ALBERTA

DEPARTMENT OF CIVIL ENGINEERING

Applications are invited for two positions at the rank of Assistant or Associate Professor. Rank and salary will depend on qualifications.

One position is in STRUCTURAL ENGINEERING. The second position is in GEOTECHNICAL ENGINEERING, specifically the application of numerical methods to field problems. Appointments effective July 1970 if feasible.

Submit applications with curriculum vitae and names of referees to Chairman, Department of Civil Engineering, University of Alberta, Edmonton, Alberta, Canada. Replies confidential.

(210)

WINDWARD ISLANDS BANANA RESEARCH SCHEME

FRUIT QUALITY RESEARCH OFFICER

Applications are invited for the post of Fruit Quality Research Officer. The successful candidate will be part of a research team investigating banana quality in a comprehensive manner, conducting experiments, observations, surveys and analyses pertaining to the improvement of quality of Windward Islands' banana. His main duties will be agronomy, field handling and packaging of bananas.

Minimum qualifications are a degree in agronomy, agriculture, plant physiology or agricultural biochemistry, together with some experience in field experimentation and/or statistics. An interest in practical mechanics and simple construction would be most useful.

The initial salary scale is $EC7,440 (£1,550) by $EC432 (£90) to $EC10,032 (£2,090) by $EC432 (£90) to $EC12,624 (£2,630) and conditions of service are based on those of the University of the West Indies.

Applicants, giving the candidate's background, together with the names of two referees, should be sent to the Director of Research, Windward Islands' Banana Research Scheme, from whom further details may be obtained at the following address:

P.O. Box 115,
Castries,
St. Lucia,
West Indies.

(489)

UNIVERSITY OF WALES

UNIVERSITY COLLEGE OF SWANSEA

SECOND CHAIR OF GEOGRAPHY

Applications are invited for the Second Chair of Geography in the department of Geography.

Further particulars, quoting reference No. B6, may be obtained from the Registrar, University College of Swansea, Singleton Park, Swansea, Glam. SA2 8PP, by February 21, 1970.

ANEURIN DAVIES.
Registrar.

(383)

UNIVERSITY OF MALAWI

Applications are invited for the following posts tenable from September, 1970. Although the staff appointed will be attached to Soche Hill College they will also be required to teach at Chancellor College. In all posts teaching experience in secondary schools or teacher training colleges is desirable:

(a) BIOLOGY. Lecturer—degree in Biology (Botany and Zoology) with a special interest, preferably in Ecology required. Research opportunities in terrestrial and aquatic ecology are available.

(b) CHEMISTRY. Lecturer—degree in Chemistry required with a subsidiary qualification in Physics.

Salary scales (including expatriate addition): Senior Lecturer, £2,500 to £2,800 per annum ; Lecturer, £1,340 to £2,250 per annum plus University addition of £360 per annum OR salary supplemented by £275 per annum (normally tax free) in appropriate case under British Expatriates Supplementation Scheme. Gratuity ; Superannuation Scheme transferable with F.S.S.U., family passages ; various allowances ; biennial overseas leave.

Detailed applications (six copies), naming three referees, by February 27, 1970, to Inter-University Council, 90/91 Tottenham Court Road, London, WIP ODT, from whom particulars are available.

(469)

AGRICULTURAL RESEARCH COUNCIL requires an ABSTRACTOR at its Weed Research Organization, near Oxford. The duties include abstracting and dealing with scientific inquiries in the field of weed control. A degree in agriculture or a biological science is desirable ; an ability to write clear, concise English is vital and a knowledge of either Dutch or a Scandinavian language and a willingness to acquire proficiency in the alternative language is essential. Salary according to age and experience in scales either (i) £872 (age 21) to £1,208 (age 26) (maximum starting pay) rising to £1,454 or (ii) £1,590 rising to £2,006.—Application forms and further details from Secretary, Weed Research Organization, Yarnton, Oxford OX5 1PF, quoting 2/70. Completed applications to be returned by February 20, 1970.

(471)

UNIVERSITY OF BRITISH COLUMBIA

INSTITUTE OF OCEANOGRAPHY

Applications are invited for a position in zoological oceanography in this Institute in the Faculty of Graduate Studies. There are twelve faculty members and thirty-five graduate students in various aspects of oceanography. Qualifications required are appropriate to the duties, which are to carry out research, to supervise graduate students and to present lectures at upper and graduate levels. The preferred field of research is in marine ecology with emphasis on zooplankton crops.

The position will be available in August, 1970 ; rank and salary will be appropriate to the appointee's qualifications and experience. Base salaries, on a twelve month basis, are at present: Assistant, $9,500 ; Associate, $11,700 ; and Full Professor, $15,800 plus 10 per cent superannuation and other benefits equivalent to about 5 per cent of salary. Appointments are generally made jointly in Oceanography and the appropriate department ; appointees are encouraged to take part in departmental activities.

Applications should include a curriculum vitae (academic training, professional experience and publications), the names of three referees, and an indication of the type of research projects which are proposed. They should be sent to: Director, Institute of Oceanography, University of British Columbia, Vancouver 8, B.C., Canada, to whom inquiries should be directed.

(314)

UNIVERSITY OF EAST AFRICA

THE UNIVERSITY COLLEGE, DAR ES SALAAM

DEPARTMENT OF STATISTICS

Applications are invited for the following appointments in the Department of Statistics of the Faculty of Arts and Social Science:

1. PROFESSOR/READER IN STATISTICS. Special interests of the Department include: econometrics, computer methods, experimental design. Experience of educational administration would be an added recommendation.

2. SENIOR LECTURER/LECTURER. Two vacancies available. Preferably with at least several years of professional experience on: Mathematical Statistics, Economic Statistics (Econometrics) or theory of decision.

Salary Scales: Professor, £EA3,150 per annum; Reader, £EA2,540 to £EA2,825 per annum; Senior Lecturer, £EA1,950 to £EA2,615 per annum ; Lecturer, £EA1,350 to £EA2,230 per annum (£EA1 = £1 3s. 4d. sterling.) Salary supplemented in range £612 to £1,068 per annum (sterling) and education allowances and childrens' holiday visit passages payable in appropriate cases under British Expatriates Supplementation Scheme. F.S.S.U. Family passages ; biennial overseas leave.

Detailed applications (six copies), naming three referees, by February 26, 1970, to Inter-University Council, 90/91 Tottenham Court Road, London, WIP ODT, from whom particulars are available.

(472)

UNIVERSITY OF SYDNEY

LECTURER IN MECHANICAL ENGINEERING

Applications are invited for the above-mentioned post. The appointee will assist in planning and teaching of undergraduate and graduate courses relating to dynamics of linear and non-linear mechanisms and control systems and pursue original research in one of these or a closely allied field. Salary range: $A5,400 to $A7,300 per annum.

Further information is available from the Secretary-General, Association of Commonwealth Universities (Appts.), 36 Gordon Square, London, W.C.1. Applications close on March 2, 1970.

(512)

UNIVERSITY OF NOTTINGHAM

DEPARTMENT OF CHEMICAL ENGINEERING

Applications are invited preferably from persons with industrial experience for the post of ASSISTANT LECTURER or LECTURER in Chemical Engineering. Salary in the range £1,240 to £1,470 (Assistant Lecturer) or £1,585 to £2,850 (Lecturer).

Further particulars and forms of application, returnable not later than March 2, from the Staff Appointments Officer.

(476)

COUNSELLOR (SCIENTIFIC)

British Embassy—Moscow

£4170—£4745

This appointment is made in connection with the promotion of co-operation between the UK and the USSR under the Anglo-Soviet Technological and Cultural Agreements. The Scientific Counsellor is responsible to HM Ambassador advising him and Embassy staff on scientific and technological affairs and also reporting home on trends and developments in this area recommending policies for their support. To do this he will need to establish personal contacts with Soviet scientific organisations.

Candidates should normally have a first or second class honours degree in science or engineering. Preference will be given to candidates with experience of dealing with industry and government departments and in the conduct and management of research. A good knowledge of Russian or an ability to become fluent is essential.

Salary will be in the above range (graded Senior Principal Scientific Officer) together with Diplomatic Service Allowances. The vacancy occurs in September 1970 and is for a period of 2 years.

Fuller details and an application form may be obtained by writing to ***Miss B. C. Taylor, Department of Education and Science, Curzon Street, London W1Y 8AA, (01-493 7070 ext. 311).*** *Closing date 20th February 1970.*

(550)

UNIVERSITY OF BELFAST

DEPARTMENT OF MECHANICAL ENGINEERING

The Senate of The Queen's University of Belfast invites applications for the following posts from October 1, 1970, or other date, as a result of reorganisation and expansion in the Department of Mechanical Engineering: (a) Senior Lectureship in Industrial Engineering to initiate undergraduate and postgraduate studies in this field ; (b) Three Lectureships in Mechanical Engineering. Candidates should preferably have interests in Thermodynamics or Fluid Dynamics or Dynamics and Control.

The salary range for a Senior Lectureship is £2,800 to £3,670 and for a Lectureship £1,585 to £2,850. Both scales carry contributory pension rights under the F.S.S.U. Initial placing on the salary scales will depend on qualifications and experience. Applications should be received by February 28, 1970.

Further particulars may be obtained from The Secretary, The Queen's University of Belfast, Belfast, BT7 1NN, Northern Ireland. (547)

UNIVERSITY OF NOTTINGHAM

DEPARTMENT OF THEORETICAL MECHANICS

Applications are invited for an **ASSISTANT LECTURESHIP** or **LECTURESHIP** within this Department. Candidates should be qualified in any branch of **STATISTICS, OPERATIONAL RESEARCH, APPLIED MATHEMATICS** or **NUMERICAL ANALYSIS**. The duties of the successful candidate will include responsibility for the teaching of statistics to students of engineering and mathematics-with-engineering. The appointment will be effective from September 1, 1970

Salary within the £1,240 to £1,470 (Assistant Lectureship), or £1,585 to £2,850 (Lectureship).

Further particulars and forms of application, returnable not later than March 2, 1970, from the Staff Appointments Officer, The University of Nottingham, University Park. (561)

RADIOBIOLOGIST

A graduate research worker with interest or experience in mammalian radiobiology and its application to radiotherapy is required for a post in the Churchill Hospital Research Institute. The successful applicant will join an interdisciplinary group studying various aspects of tissue and tumour growth and the effects of ionizing radiation and drugs upon it. Salary according to age, qualifications and experience.

Replies to Dr. R. J. Berry, M.R.C. External Scientific Staff, Radiobiology Laboratory, Churchill Hospital, Oxford. (441)

AREA LABORATORY

KING EDWARD VII HOSPITAL WINDSOR

Wanted immediately—SENIOR GRADE BIOCHEMIST in the Department of Chemical Pathology, with salary according to National scales.

This well equipped Department serves 1,000 beds, of which 600 are acute, at the District Hospital Centres at Windsor and Ascot, together with the Maidenhead Hospitals, and a large volume of work is undertaken for General Practitioners. Opportunities exist for useful research and working for the M.C.B. Applications to the Senior Pathologist, Area Laboratory. (544)

UNIVERSITY OF BRISTOL. DEPARTment of Zoology. Applications are invited for the post of Research Assistant to undertake physiological investigations on animals in transition from water to land. Applicants should be interested in problems of respiratory adaptations and experience in respiratory work would be an advantage. Graduates and postdoctorals will be considered. Salary will depend upon qualifications and experience and will be in the range of £800 to £1,470 per annum.—Applications, giving the names of two referees, should be sent to Professor G. M. Hughes, Department of Zoology, The University, Woodland Road, Bristol, BS8 1UG, by February 18, 1970. (501)

UNIVERSITY OF SOUTHAMPTON

DEPARTMENT OF ELECTRICAL ENGINEERING

EXPERIMENTAL OFFICER

Applications are invited from suitably qualified candidates for this post. The successful applicant will be required to take responsibility for the design, construction and preparation of electronic measuring equipment for research purposes.

This is a senior appointment and candidates will be expected to have a university degree or professional qualification, together with appropriate experience.

Salary scale: £1,240 to £2,045 per annum plus F.S.S.U.

Applications, giving details of age, qualifications and the names of two referees, should be sent to the Deputy Secretary, The University, Southampton, SO9 5NH by February 28, 1970. Quoting Reference Na. (560)

NATIONAL INSTITUTE FOR RESEARCH IN DAIRYING

(UNIVERSITY OF READING)

ASSISTANT EXPERIMENTAL OFFICER/EXPERIMENTAL OFFICER with an interest in biophysics required to assist in the running of an analytical ultracentrifuge. The work would involve participation in several research projects, one of which would be concerned with the characterisation and interaction of milk proteins. Salary scales: A.E.O., up to £940 (age 22) to £1,208 (age 26) to £1,454; E.O., £1,590 to £2,006. Qualifications: Degree, Dip.Tech., H.N.C. or equivalent. Under 22, minimum qualification is two G.C.E. " A " levels in scientific subjects.

Apply to Secretary, N.I.R.D., Shinfield, Reading, quoting two referees and reference 70/3. (485)

MARINE LABORATORY, ABERDEEN

DEPARTMENT OF AGRICULTURE AND FISHERIES FOR SCOTLAND

MARINE BIOLOGIST in the **ORGANIC ENVIRONMENT SECTION** (graded Senior Scientific Officer/Scientific Officer) to work on the feeding and metabolism of invertebrates as part of a general study of marine food chains and especially in relation to problems of pollution. A knowledge of biochemistry and of experimental techniques in this field is most desirable.

Qualifications: 1st or 2nd class honours degree in zoology or equivalent and for SSO at least three years post-graduate experience.

Age: SO under 29, SSO normally 26–31.

Salary: SO £1,071–£1,827, SSO £2,021–£2,491.

Prospects of permanent pensionable employment.

Application forms from the Secretary, Department of Agriculture and Fisheries, Room 172(C), St Andrew's House, Edinburgh, EH1 3DA
Closing date 27 February 1970.

(467)

Searle

SEARLE SCIENTIFIC SERVICES MEDICAL RESEARCH

This new department in High Wycombe requires laboratory technicians and junior laboratory technicians to work in the hormone laboratory. The work performed in this laboratory is in the field of medical research and involves the determination of steroid hormones and protein hormones using the latest techniques available.

Qualifications: For the technician posts applicants should possess I.M.L.T., H.N.C. or equivalent. For the junior posts O or A levels in Science or Biology are needed. Experience in laboratory work would be an added advantage but is not essential. A Hospital background is preferred to industrial experience.

Working conditions are excellent and include:

CANTEEN RECREATION CLUB PENSION FUND

Please apply to:

The Personnel Officer,
G. D. Searle & Co. Ltd.,
Lane End Road, High Wycombe, Bucks.
Telephone: High Wycombe 21124.

(549)

NEW ZEALAND

University of Canterbury • Christchurch

Applications are invited for the following positions:

ASSISTANT LECTURER IN GEOLOGY:

The appointee's duties will be to assist in the teaching of one or more of these subjects: engineering geology, engineering geophysics, applied geology.

Applications close on March 14, 1970.

Salaries are under review. **Existing** salaries for Assistant Lecturers are $NZ2,500 by $NZ100 to $NZ2,900 per annum.

Particulars, including information on travel and removal allowances, study leave, housing and superannuation may be obtained from the Secretary-General, Association of Commonwealth Universities (Appts.), 36 Gordon Square, London, W.C.1. (509)

QUEEN ELIZABETH COLLEGE (UNIVERSITY OF LONDON) CAMPDEN HILL ROAD, W.8

Applications are invited for the post of SENIOR LECTURER in the Department of BIOCHEMISTRY. The successful candidate will be required to take an active part in teaching Biochemistry to Honours B.Sc. standard and to pursue an independent line of research as well as to share in the administration of the Department. Salary range £2,770 to £3,760 plus £80 London Allowance.

Further particulars from the College Secretary, to whom applications should be sent by February 28. (517)

THE UNIVERSITY OF ASTON IN BIRMINGHAM

DEPARTMENT OF BIOLOGICAL SCIENCES

READER/SENIOR LECTURER IN BIOCHEMICAL ENDOCRINOLOGY

Applications are invited from suitably qualified biochemists preferably with a medical qualification, to be responsible for the co-ordination and furtherance of hormonal and intestinal physiology research under the general direction of the Head of the Department. The successful applicant will also be expected to lecture in animal biochemistry and general physiology.

SALARY: £2,930 by £115 to £3,390 by £140 to £3,670 per annum.

Further details and application forms may be obtained from the Staff Officer (Ref. No. 734/6), the University of Aston in Birmingham, Gosta Green, Birmingham 4, to whom applications should be forwarded within 14 days of the appearance of this advertisement. (542)

UNIVERSITY OF LONDON

BRITISH POSTGRADUATE MEDICAL FEDERATION, INSTITUTE OF LARYNGOLOGY AND OTOLOGY
330/336 Gray's Inn Road, W.C.1

BIO-ACOUSTICAL INVESTIGATION

There is a vacancy for a graduate research assistant which could be filled by a candidate preferably experienced in Experimental Psychology, Experimental Physiology or other appropriate field. Salary £1,435 to £1,665.

Application to: The Secretary-Administrator, Institute of Laryngology and Otology, 330/336 Gray's Inn Road, W.C.1. Closing date February 14 1970. (304)

And that's exactly what Pye Unicam have done with the world-famous Unicam SP90 Atomic Absorption Spectrophotometer. It's now the Unicam SP90 Series 2, but it's not just the name that has changed. Absorbance or energy scales can now be presented in linear form on the integral meter or on a pen recorder, with continuous scale expansion of up to 10x for absorbance. Results can also now be shown on a digital display and printout accessory. The sensitivity specification has been increased as a result of improved hollow cathode lamps and excellent optical quality, whilst still preserving the outstanding detection limits. And, of course, there are all the first-class features and accessories associated with the original SP90 spectrophotometer–like flame emission facilities, a wide choice of flame and burner systems (including nitrous oxide with a new burner head), a three-lamp turret and automatic sampling. For more information and full technical details on this new instrument and the range of hollow cathode lamps, write to Pye Unicam Ltd.

This unique water still is in use in a number of research establishments and hospitals where water of the highest purity is essential.

PRICE, complete with heater and all electrical equipment 230 volt (a.c. only)—**£45-0-0**

Obtainable only from

L. V. D. SCORAH, M.Sc.

(Manufacturer of the "SCORAH" Blowpipe)

44 NORTHFIELD ROAD, KINGS NORTON,
BIRMINGHAM, 30. 021-458 1885

The SCORAH Automatic Electric all glass WATER STILL (patented)

Automatic Can be left on without attention. Heater current cuts off if water supply is interrupted, or inadequate or forgotten. When receiver (5 litres capacity) is full, current cuts off. When distilled water is drawn from receiver, the still resumes operation until receiver is refilled.

Purity Electrostatically charged condenser droplets can pick up fumes, dust and air-borne organisms from the laboratory atmosphere. The design of the receiver vessel ensures absence of such contamination.

Efficiency Heater of Scorah design and manufacture, consumption 1,700 watts, output 2.4 litres per hour (the full theoretical yield). Cost 3½d. per gallon at 1d. per unit.

Safety The heating element is out of contact with the feed water, thus eliminating danger from "live" water supply or electrolytic effects or "burn out".

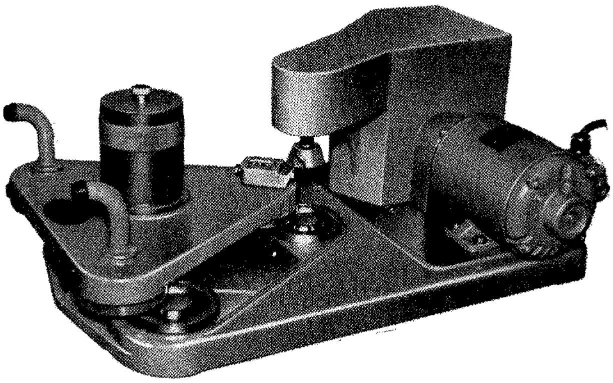
Assembly No retort stands or clamps are required. The 2½-in. diameter ball joint gives a strainless set-up. Outlet cap on boiler for quick periodical drain-off of sediment. The still may be installed on a shelf or platform about 1 ft. above bench level near a sink and enclosed in a transparent plastic cover to keep out dust.

Phoenix heat-resisting glass. Interchangeable ground glass joints.

CUTROCK

CROFT PARALLEL GRINDING MACHINE (MOTOR DRIVEN)

For precision grinding of thin sections and fossils



The travelling carriage of the machine moves in a circular track over the grinding plate controlled by steel balls running in precision machined tracks. Mounted in the centre of the carriage is a metric micrometer which houses the specimen holder. When the carriage is in the grinding position as illustrated, the micrometer can be adjusted until the specimen is in contact with the grinding plate, at this point the reading should be taken and then the amount to be ground off should be set on the micrometer. The specimen holder will lift by this amount and as the machine grinds the holder will return to its setting position, which once reached will stop any further grinding of the specimen even if the machine continues to run.

Grinding plates can be supplied in zinc, copper, cast iron, glass or lead.

NATURE Volume 225 FEBRUARY 14, 1970

Repentance Postponed on Polytechnics

One of the conventions of British public life is that a reshuffling of ministerial posts in the government can be decently regarded as an opportunity for making small adjustments of policy. A new minister, like a new broom, can for a time act a little more freely than his predecessor, and can in the process jettison or at least modify policies which may have become less popular with the passage of time. All this is widely accepted, which is why it is a great misfortune that Mr Gerald Fowler, the new minister of state at the Department of Education and Science, has this week nailed his colours to the rickety mast of the policy on polytechnics and their place in higher education which has been evolved or at least accreted in the past few years. At the same time, in a recent article in the *Guardian*, Mr Fowler went a long way to harden the gulf which now divides the British system of higher education into two discordant parts. The way things are going, there is a serious danger of permanent damage to the system as a whole.

A convenient text for this assertion is Mr Fowler's definition of the distinction between universities and polytechnics. He says the two kinds of institutions will be "sharply differentiated", and that polytechnics will be recognized by the diversity of their student body as well as by the diversity of the courses which they offer. Mr Fowler goes on to express his hopes that the thirty polytechnics—fourteen have so far been established—will "undertake sponsored research projects" for industrial companies, although he does not think that research will ever play a very large part in the work of a polytechnic. Rather, he says, the need is to work out ways of providing a more educative and humane foundation for vocational courses of the kind which have been the traditional bread and butter of the technical colleges. Although Mr Fowler insists that he does not want "to see a gap develop" between the polytechnics and the universities, his vision of collaboration between them seems to consist of the exchange of staff or of facilities where one institution is able usefully to complement the work of the other—a valuable enough task in all conscience, but one that is hardly likely to flourish except in exceptional circumstances.

The trouble with all this is not merely that there will inevitably grow up what Mr Fowler calls a gap between the universities and the polytechnics, but that the doctrine of the binary system will project into higher education some of the inconsistencies which have beggared British secondary education in the past few decades. How, for example, will students choose between universities and polytechnics? Will they always have a free choice, and what are the circumstances in which young men and women able to find a place for themselves at a university will voluntarily settle for a polytechnic? With the best will in the world, it is exceedingly hard to see how the innate attractions of the universities, with their cosy staff to student ratios, their facilities and their opportunities for research, will fail to skim the cream off the available supply of talent. The result, for a time at least, may well be that the student population in the polytechnics is not nearly as diverse as Mr Fowler hopes but, rather, that it will consist of those bright young men and women who have tried but failed to win a university place for themselves. It is in the circumstances a little too pious of Mr Fowler to insist that neither he nor the government will regard the polytechnics as second-class institutions—what matters, alas, is not even the truth but what the customers think. Under the present arrangements, there is a serious danger that the polytechnics will fail to attract the students and the staff which are essential to Mr Fowler's idyll.

If the new minister has not seized the chance to turn his back on these and other defects of the new proposals, what can be done? It may not be entirely outrageous to suggest that it would be possible for the universities and the polytechnics themselves to take the initiative. The objects should be plain—the integration of the divided system. Ultimately, this implies that there should be "comprehensive universities" along the lines which seem to attract the present government, but they should be built around the present universities and not separately from them. There is no reason why groups of institutions should not already make a start. The way in which the University of Manchester and the one-time Technical College (now the University of Manchester Institute of Science and Technology) have made a durable marriage is a good precedent which at the same time reveals how flexibility within the university system is limited not so much by the conventions of the governing bodies as by the rigidity of the academic departments. In the long run, the best way of pulling Mr Fowler's chestnuts from the fire will be some enterprising marriage or at least liaison between a traditional university and a polytechnic. The sooner, for everybody's sake, the better. •

What if they Forget to Pay the Piper?

THE newest budget from the United States Administration may be an intellectual masterpiece by combining acumen with information, but it is also a sombre document, full of evidence that people are now accustomed to living in a world in which expenditure on science and technology stagnates. It is true that nobody will miss the full flower of Plowshare, and that there may even be a kind of logic in the decision of the Atomic Energy Commission to finance the 200 GeV accelerator in Illinois at the expense of older and presumably duller projects, but the question now urgently arises whether it is really wise that the amount of money spent on uncommitted science and technology, and especially on basic research, should remain the same in the seventies as it became in the sixties. On the face of things, there is good reason for fearing that such a state of affairs will bring only trouble. More distantly, there is a serious risk that the continuing drain on the ebullience of the scientific community now in prospect will eventually bring about a condition in which industrialized society as a whole, not just the American, will languish.

This is why it is first important to count the blessings which the budget for 1971 contains. To begin with, there is the problem. For one thing, if Mr Nixon's people have their way with Congress, the National Science Foundation will have more to spend. That is as it should be, even if the increase is accompanied by a decrease in the amount of money for basic research provided by the other agencies—the Pentagon's Project Themis has now sunk without trace, and there will be very little surprise that it has now become necessary for NASA to give up its traditional but diminishing request for money with which to support university research. Putting the responsibility for the support of basic research with the National Science Foundation is the right strategy, and doubtless it is no accident that the NSF has already begun to respond to the commendation by the National Science Board (the NSF's board of trustees) of a pattern of research financing in which good institutions are picked out for particular rewards. Yet there is a long way to go before the NSF can properly acknowledge that a large part of its responsibility is the support not merely of scientific research but of the institutions in which it is carried out. Before that can happen, Congress will have to acknowledge more openly that public money can be legitimately spent thus. A more radical change of pattern will only be possible when the NSF has more power to its elbow and more money in its purse.

In the meantime, the signs and symptoms of penury are plain for all to see. One important change has been the way in which many of the agencies have been forced to spend a greater proportion of their funds in their own laboratories. Among the obvious dangers of such a course are those of creating institutions which are less able to change with the times that the changing needs of scientific research require. American institutions may have been especially able to change their ways in the past few years, but there are limits to what is possible in the face of adversity. A second and more serious problem is the way the new pressures may shift the initiative in research from the universities to the institutions. This is not so much a matter of scale as of temperament—a great many potential researchers may persuade themselves that life in a research institute may be preferable to life in a university when research is not considered to be an integral part of university life. But there is also the problem of scale. Nobody would find it easy to show in precisely what ways the generous spending on research and development in the decades since the Second World War has contributed to the present economic strength of the United States, but it would be a great surprise if the correlation was negative or even small.

But even economic strength is only a small term in the equation. The much more serious danger is that too much parsimony for too long may rob research of its capacity to sustain itself. The steam may condense in the cylinders. It may be too gloomy by half to fear that the comparatively gentle restrictions of the new budget could bring about such a tragedy. Yet it is also well known that modern science is substantially an invention of the past few decades. The budget men should sometimes ask themselves how much restraint for how long will be necessary to make it disappear all over again.

---

100 Years Ago

THE 25-inch Equatorial Telescope, commenced several years ago by T. Cooke and Sons, of York, for R. S. Newall, Esq., of Gateshead, is now so far completed that it has been removed from the works at York into its observatory in Mr. Newall's grounds, at Fern Deal.

The completion of a telescope with an object glass of 25 inches aperture, marks an epoch in astronomy, and its completion in England again places us in the front rank in the matter of the optical art, as we were in Dolland's time.

The history of the progress of the manufacture of telescopes since the time referred to, shows very clearly the long-lasting effects of bad legislation; for it is not too much to say that the duty on glass entirely stifled, if indeed it did not kill, the optical art in England. Hence we depended for many years upon France and Germany for our telescopes to such an extent indeed that the largest object-glasses at Greenwich, Oxford, and Cambridge are all of foreign make.

From Nature, **1**, 409, *February* 17, 1870. *The instrument, described as a "monster among telescopes", sported a cigar-shaped tube* 32 *feet in length and weighed nearly* 9 *tons.*

OLD WORLD

IMPERIAL COLLEGE

Architecture of Discontent

After six years of negotiations, Imperial College, London, has unilaterally called off its plans for a merger with the School of the Architectural Association. Lord Penney, rector of Imperial College, has said on behalf of the governors that the basis for a merger no longer exists but Mr John Lloyd, the principal of the school, claims that the governors acted with "a total lack of good faith" and says that he cannot approach Imperial College again. Talks had continued until the last moment, and the break seems to have been a complete surprise; the University Grants Committee had approved the merger, which was to be dependent on the raising of £500,000 by the Architectural Association for new buildings. The lease on the association's present accommodation expires in 1976.

Two explanations for the sudden decision are being aired. The first, and most widely favoured, turns on the question of student power. The school of the Architectural Association (AA) has a tradition of liberal student representation, and was founded by students in 1847. Further, it appoints staff only for short periods and does not provide the life tenure that a university would give. Both of these points go against the grain at Imperial College, where the students are already seeking more involvement in administration. The second view is that the decision was forced by an anti-interdisciplinary lobby, and the idea of a conflict between architectural and engineering interests was even raised in a letter to the *Times* (February 9) by Professor Colin Buchanan of the department of civil engineering at Imperial College.

The AA itself apparently gives priority to the first explanation, and its council resolved on Monday night that there was, in its opinion, "a fundamental conflict of educational objectives". So, too, do the students at Imperial College, according to the union president, Mr Piers Corbyn. On Tuesday more than five hundred of them, accompanied by members of the staff and some students from the AA, left a wreath at Lord Penney's home and a message in his office.

One of the AA's main objectives at the moment is to guarantee the future of its students, many of whom take five-year courses. Because its lease ends in 1976 it cannot yet offer a complete course to prospective students for this autumn. Since the school is privately owned and cannot afford to continue beyond then without outside help, it seems that its future probably lies within the state system. Discussions on Monday with Mr Gerald Fowler, Minister of State at the Department of Education and Science, were said to be encouraging, and the immediate aim has become the investigation of "every possible alternative" now that the Imperial College plans have fallen through. Meanwhile the AA's president, Miss Jane Drew, who is on a fund-raising tour in the United States, has an even more urgent task ahead of her.

In the midst of the debacle the governing body of Imperial College has published its report for 1968–69, which was completed too soon to say anything about the architectural crisis beyond noting simply that there was agreement in principle ever the merger. But other problems are revealed. The appeal for £2 million, launched last January to bring in funds for building and research (see *Nature*, **221**, 118; 1969), has made "steady, if disappointing progress", reaching £400,000 by July 31, but with a better response from city financiers than from industry. Nearly all the money that has come in so far has been spent on providing or converting student houses. In spite of a forecast deficit, however, the college managed to reach a surplus of £62,691 by the end of the year, by enforcing a 6 per cent cut in expenditure. Present estimates for 1969–70 suggest a likely deficit of £50,000, mainly because of salary increases, and more cuts may be needed next year.

During the session there were 3,792 full time students, some 1,200 short of the figure that the University Grants Committee thinks the college can take when its site is fully developed. How this growth is to be directed over the coming decade is now occupying a steering committee under the chairmanship of the pro rector, Lord Jackson. The committee is asking the college's departments how they intend to expand, and hopes to report during the first half of 1970 on what might be done.

COMPUTERS

ICL at the Select Committee

The spectre of IBM haunted the room at Westminster where the Select Committee on Science and Technology was taking evidence from International Computers Ltd last week, and it will no doubt loom over the rest of the hearings on the British computer industry. The managing director of ICL, Mr Arthur Humphreys, put his company's plight in a nutshell: "There is no problem in the computer business which would not be solved by the demise of IBM". But IBM cannot be exorcised by wishful thinking, and the subcommittee appointed by the Select Committee to carry out the investigation under the chairmanship of Mr Airey Neave wanted to know if anything more concrete could be done. Mr Humphreys and his colleagues made plain their feeling that the British Government could do more to help. For example, American computers have been ordered for the Army Pay Corps and for the Home Office crime-fighting system, and this was affecting the credibility of the ICL System-4 in the market place. It is proving difficult to sell System-4—teething troubles have not helped—and most of the company's business will continue to come from the 1900 series. Another problem is the rapid turnover of senior staff, and with the forward-looking orders going to the United States there is not enough of the advanced work which encourages people to stay.

Little progress is being made in the talks on collaboration with Europe as a way of spreading the competition with IBM, Mr Eric Moonman of the subcommittee pointed out, and he wondered whether the Industrial Reorganization Corporation or the government could do anything to help. This was clearly a sensitive point, chiefly because the Aigrain proposal to cooperate on a powerful computer was the only proposal set up by industry rather than by civil servants, and pride was forcing the industry to make another effort to get the project moving before calling for help.

Mr Basil de Ferranti of ICL thought that there was "an enormous potential for success" in European collaboration, but failure would be damaging.

The subcommittee was critical of the confidential memorandum submitted by ICL, and questioned the basis for the market forecasts which it contained and why it made no mention of markets outside the United States and Europe—such as Japan, Mr Moonman said. Mr Humphreys had a sad tale of how the Japanese market is denied to ICL by the fearsome trinity of intense competition, high import duties and the quota system. Another difficult market is eastern Europe, where the orders rather awkwardly tend to be for equipment which is outside the embargo rules. Mr Humphreys thought that ICL was being used to get the embargo system lifted.

The success of IBM was attributed by Mr Humphreys to the ready-made market which they had from their punched card business, and to the purchasing policy of the US Government. IBM has had orders for large batches of particular computer models from the US Government, but ICL had never been asked for more than four of a particular type of computer at once. This was the secret of IBM's success, and not their research expenditure, which was not extraordinary.

The ICL representatives went away impressed by the subcommittee's knowledge of the computer industry—the computer appreciation course at Imperial College which the members attended obviously paid off—but few ideas were forthcoming from the ICL side of what measures the government could reasonably take to help.

COMPUTERS

How IBM Forged Ahead

SOME essential reading for Mr Airey Neave's subcommittee (see page 575) has just been published by the OECD in the form of a survey of the computer industry in OECD countries—the latest in the remorseless series on "Gaps in Technology" which examine the disparity between the United States and the rest (available from HMSO, 21*s*). What it boils down to, of course, is why IBM is so far ahead. In most European countries, according to the report, IBM was responsible for between 60 and 70 per cent of the value of computers installed in 1967 (an exception was Britain, where ICL brought IBM's share down to 39 per cent), and in the United States IBM has a similar dominant position over other US manufacturers.

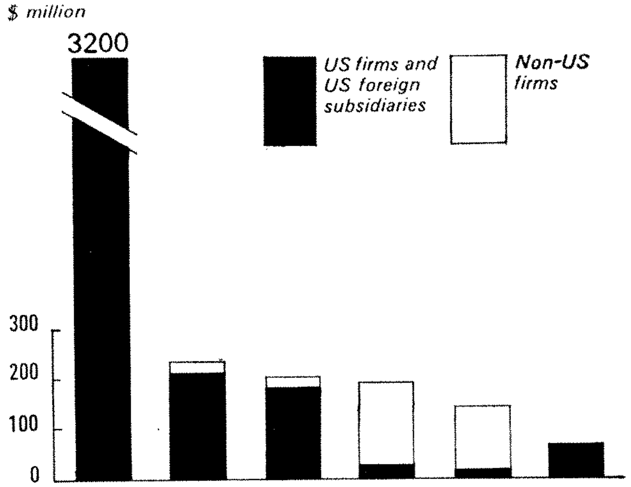
The investigation of the British computer industry now taking place makes the OECD more topical than it deserves to be—the report was prepared for the meeting of science ministers of OECD countries in March 1968. This means that the statistics which are the chief virtue of the report are out of date, which is a pity because the group of experts responsible obviously went to great trouble to make accurate statistics out of meagre data supplied by member countries, and one of their grumbles is that governments ought to have a better idea of what is going on in their countries.

What the report shows is that the pre-eminence of the US computer industry was not due to a deliberate policy on the part of the government, a lesson which the subcommittee will no doubt take to heart. Rather it has been the existence of the large government market, and the large amount of government financing of R and D work compared with other countries which has stimulated the industry. But IBM seems to have had less than its fair share, and one definite policy which the report mentions is that companies other than IBM are preferred for government contracts so as to stimulate smaller companies. The IBM share of the Department of Defense market, for example, is less than its share of the US computer market as a whole, and when IBM computers are used they tend to be leased (in common with the computers of other large companies such as NCR and GE) rather than bought. Yet these factors seem not to have harmed IBM, and the moral which the report points to is that successful companies are those with products which suit the business market rather than the scientific or military market.

This is where Britain missed the bus, and the report criticizes the failure to sell the LEO I computer which remained one of the first machines designed for business uses until five years after it was completed. This was the computer designed for the Lyons food chain by the Lyons Electronic Office in cooperation with Cambridge University. The report also raps the UKAEA and the Treasury for their unencouraging attitude, but praises the NRDC for ordering some of Ferranti's early computers.

It is clear that the strong connexions in the office equipment field which predated the entry of IBM into the computer business are not the whole explanation of IBM's success—the ill-fated French firm Bull had a marketing organization which was equivalent to that of IBM. Neither was IBM first into the market, and here it was beaten by Remington Rand with Univac I in 1951. Rather the report attributes the success of IBM to three factors: (1) an appreciation of what the customers wanted, in particular the importance of software; (2) the ability to stimulate the market by developing new products and helping customers; and (3) good internal organization.

What can be done in the face of US competition? One approach is to concentrate on particular aspects of the computer business, and the report mentions process control by computer, and the manufacture of



The world computer industry in 1966. Estimated shipments in the main computer producing countries, from *The OECD Observer*.

terminal equipment for time-sharing systems as areas which are wide open. Although "the example of the United States also shows that a clearly delineated policy is not a prerequisite to successful support on the part of the government", the report says that governments can help to produce the conditions for a flourishing industry. For example, governments can help by encouraging education in the computer sciences, by supporting new and fast growing areas of the industry, and by improving the communications network (chiefly the telephone system) so that the development of time-sharing computers will not be hampered by expensive and unreliable communications.

POLLUTION

Sewage Works are Inadequate

Environmental pollution is fast becoming the talking point of the British Establishment. Only five days before the Duke of Edinburgh spoke at the European Conservation Conference in Strasbourg, the House of Lords debated the pollution of British rivers. Lord Kennet, Parliamentary Secretary to the Ministry of Housing and Local Government, gave a comprehensive survey of the inadequacies of sewage treatment in Britain and outlined government thinking on new measures of control, although, in the absence of a comprehensive survey of the situation, few concrete proposals emerged.

Three out of every five local authority sewage works are producing effluent which is below standard and this, said Lord Kennet, is only part of the story. We do not know how much effluent is being poured directly into British rivers by industry, nor just how dirty our rivers are. Before the government can impose new regulations for sewage disposal, he said, a complete survey of British rivers must be carried out, and this is at present being undertaken by all the river authorities. Preliminary results of the survey, which should be available in June, will give some indication of changes in the condition of the rivers since 1958, but until then, "action taken before ignorance is dispelled will be capricious action".

Some hints of the government's intentions on new regulations were, however, given by Lord Kennet. Penalties for discharging insufficiently treated sewage need to be brought to a more realistic level, he said, because many firms find it cheaper to risk being fined than to spend the substantial sums needed to meet the standards demanded by the river authorities. The government is also looking into the suggestion that pollution of rivers should be an absolute offence, whether caused knowingly or not.

Lord Molson, who opened the debate, accused the government of soft pedalling on river pollution. In 1966, borough treasurers stated that 60 per cent of the effluent being poured into rivers failed to comply with standards laid down by river authorities, but these standards are difficult to enforce. First, sewage authorities may appeal to the Minister of Housing and Local Government that standards are unreasonable, and Lord Molson accused the government of showing a bias towards the sewage authorities. A circular sent by the Minister of Housing to the river authorities in 1968 pointed out that standards laid down for industrial effluents must be justified, whether they are unusually stringent or not. Second, river authorities have no right of inspection of sewage works and, third, Lord Molson said that the fines for river pollution are "hopelessly inadequate".

Lord Molson said that the cost of sewage treatment, which is running at about £100 million a year, should be increased to about £300 million, and he indicated that this could be done by transferring money from housing, roads and so on. Such a step would go far towards meeting water requirements for the end of the century and would be more desirable than submerging additional areas of the Peak District to provide pure water.

One reason why sewage works are outdated, and river pollution is not being tackled fast enough, was suggested by Lord Nugent, chairman of the Thames Conservancy. There are no votes in sewage, he said, and local authorities are reluctant to spend ratepayers' money on sewage works when there are more attractive projects to be undertaken.

COUNTRYSIDE

Cars Curbed in Peak District

by our Planning Correspondent

For the first time in Britain, there is to be an attempt this summer to control weekend traffic in a beauty spot in a national park. Along a four mile stretch of road in the Goyt Valley in the Peak District National Park, motorists, other than those with permits, will be banned from using their cars at summer weekends and on public holidays from July to September this year and from Whitsuntide to September in 1971. There will, instead, be four new car parks at strategic points for up to 300 cars, marshalling arrangements and a mini-bus service to take people to picnic sites and nature trails. Walkers, cyclists, pony trekkers and people who need access to the land in the area will be allowed through the traffic free zone.

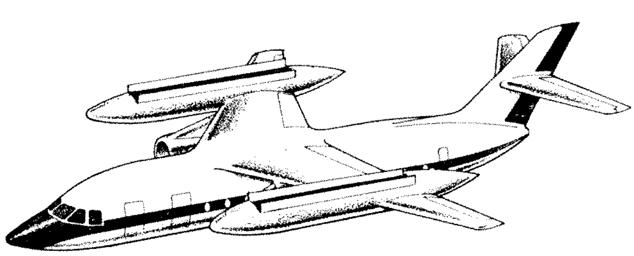
The experiment, which will last for two years and which has yet to be finally approved, is being organized by the Countryside Commission in cooperation with the Peak Park Planning Board using new powers now possible under the Road Traffic Regulation Act of 1967 and the Countryside Act of 1968. The scheme will cost the commission about £17,500 over the two years, but it is hoped that the motorist, by accepting some restrictions on the free use of his car in the Goyt Valley, will be able to enjoy the tranquillity of the countryside which he is at present destroying. The experiment, although on a small scale, is important because it could be the forerunner of similar schemes in parts of other national parks in Britain which are under heavy pressure from motor cars at certain times of the year. Parts of the Lake District National Park, for example, badly need some sort of traffic management in the summer months. But, according to the Friends of the Lake District, it is not just the weekend traffic that is threatening the beauty of the Lake District and the enjoyment of the majority of its visitors. In their latest newsletter the Friends describe the threats of new road works, increasing numbers of caravans, powerboats on the lakes, abandoned motor cars, and the removal of water-worn rock from attractive limestone areas in and around the Lake District. The Friends are particularly opposed to the route and scale of the proposed new road to by-pass

Ambleside in the heart of the national park. Apart from the incongrousness of such a road which would be dual carriageway in parts, the Friends feel that it may become unnecessary when heavy goods traffic and motorists bound for Scotland start to use the new M6 motorway extension which will by-pass the Lake District.

AVIATION

Taking Off for the Eighties

By the end of the year the Ministry of Technology should be in a position to decide what encouragement to give to the proposed types of vertical take-off and landing (VTOL) aircraft designed for inter-city links on a European scale for the 1980s. About £50,000 has already been spent by the ministry on studies of various aspects of future VTOL civil operations and rather more is likely to be spent in the current year. A lot more than the flying craft is involved in adopting this system of getting from A to B. Where are the vertical landing craft to land in city centres ? Will the noise they make doing it be acceptable in a built-up area ? Will the air traffic control features be compatible with control procedures for the conventional aircraft which they will supplement rather than replace ? Will the passenger demand for faster inter-city travel be sufficient to justify not only the high cost of development but the higher fares predicted for the service ? Definition on all these points is being sought in parallel with ministry assessment of three design submissions of craft from industry. Hawker Siddeley Aviation, Westland Helicopters, Ltd, and the British Aircraft Corporation were invited to present their ideas, and reports several inches thick which were delivered to the ministry at the turn of the year are still under study.



Hawker Siddeley Aviation fan-lift VTOL configuration. Eight lift fans are carried in each wing pod for vertical flight.

At the completion of this process it would be expected that one or more of the more promising design proposals would be subsidized by MinTech to the point of detailed feasibility. A decision on whether to go ahead on the system as part of a total travel network for Europe for the 1980s is not required till 1971. Possibly the most critical factor is the actual supply of suitable sites in city centres. A metropolitan VTOL port requires a minimum area 1,000 metres in diameter which is free of noise-sensitive institutions such as schools and has good ground transport connexions. Such sites do not hang about on the market long. London is a particular problem. Surrey Docks has just joined the two other possible candidates—Kings Cross goods yard and Nine Elms (already earmarked for the new Covent Garden). But will any of these still be available when MinTech comes to take decisions in maybe 18 months time ? It is pointed out that it is no part of MinTech's task to implement a VTOL inter-city service and that no commitments have yet been made.

The aircraft proposals divide into two categories—rotorcraft and fan-lift aeroplanes. The Westland proposal employs the same power units for lift and forward flight, namely rotors that are turned through 90° by a tilting wing. One of the Hawker Siddeley proposals also employs rotors—the unconventional controlled circulation rotor originally developed by the National Gas Turbine Establishment, Pyestock. Two of these would be used for the lift phase only; they are folded and stowed for forward flight and this is the most problematic aspect of the design. This configuration would be expected to be faster than the tilt rotor craft and to have a more modern image.

Hawker Siddeley has studied fan-lift for 10 years and makes use of it in what appears to be the most attractive of the proposals put forward. The fan-lift engine is a specialized form of jet engine in which the axis is at right angles to the direction of flight and so provides thrust for vertical ascent. As with the company's other submission, separate power plants are employed for forward and vertical flight. Such an airliner might be faster than VTOL, has a very modern image but would have high maintenance cost and fuel consumption.

BAC has limited its proposals to various ways of shortening the take-off of its conventional aircraft, so that its submission is a STOL rather than a VTOL proposal. The airliners in view are all in the 100-passenger bracket.

At present, largely through Hawker Siddeley's development of the military VTOL, the Harrier, and Rolls-Royce work on specialized "lift" engines, Britain is considered to have a respectable world lead in VTOL. But there is much activity in both France and Germany, and there would seem an excellent argument for joint European development here. The weakest aspect of MinTech's sensible "phased approach" strategy is that little headway has been made in discussion with our European neighbours.

Meantime, as the results of the half dozen or so background studies come in, a valuable body of facts previously unavailable is being built up. They will be of interest much beyond the immediate VTOL terms of reference, particularly those carried out at Southampton and Leeds Universities on traffic patterns and passenger attitudes. Altogether 30,000 individual journeys have been analysed by Southampton and 10,000 questionnaires collected by Leeds. Neither report has yet been published.

SCIENCE RESEARCH COUNCIL

Equality for Engineering

By creating separate engineering and science boards the Science Research Council had set engineering on a manifestly equal footing with science, Professor Sir Brian Flowers told the Institution of Electrical Engineers in London last week. Moreover, by placing the interdisciplinary sciences of metallurgy, computing science, polymer science and materials under the aegis of the Engineering Board, the Science Research Council had clearly indicated which way it wanted university research to develop.

As an example of the SRC's policy towards the growing number of interdisciplinary activities, Professor Flowers explained how control engineering had been concentrated into three main centres, at Cambridge, Imperial College and the Manchester Institute of Technology, each with extensive computing facilities. The SRC had invested more than half a million pounds in the Cambridge control group alone, where industrial applications have included a model of a hot steel strip rolling mill and the control of once through boilers required in the nuclear power field. Computing science is one of the major emerging disciplines where the SRC is spending more than £2 million, with major groups centred in Edinburgh, Manchester and Cambridge.

The SRC was also increasing its interest in social problems, Professor Flowers said. On the study of transport systems, he hinted that with the findings of the SRC review panel at present under discussion it was likely that the SRC would be able to double its present commitment of £280,000 in this field. The SRC would also participate in defining the role of the new transport and environment centre, recommended in Lady Sharp's recent report *The Men for the Job* and now accepted by the government. The deliberate exploitation of spin-off was another important factor in SRC policy, Sir Brian said, but despite the growing preoccupation with applied science the SRC had no intention of neglecting the pure sciences. He also hoped that pure mathematics would be resuscitated under the new Science Board.

Lord Bowden, replying to Professor Flowers, said that he greatly welcomed the SRC's new posture on engineering. He could never understand the logic of the Haldane Report of 1918, for so long the bible of the research councils, in which the control of research was vested in those who had no interest in the outcome. "It's like entrusting the direction of Covent Garden to someone primarily interested in acoustics", he said.

He thought the idea of the University Grants Committee and the SRC working under different philosophies was a constructive one, with the UGC trying to spread grants evenly and SRC being selective according to merit. But pure science was still getting too much of the cake. He suggested that astronomy should be financed by the Arts Council as it satisfied the required test of giving considerable intellectual satisfaction to a tiny fraction of the community.

EDUCATION

Royal Society's Committee

The Royal Society has underlined its interest in education with two new initiatives. It has appointed a full-time education officer and set up a standing committee on education under the chairmanship of Professor C. C. Butler. Professor Butler, who was joint chairman of the working party of the Schools Council and the Standing Committee on University Entrance which put forward the controversial proposals for "Q" and "F" level examinations, has said that the new committee would be concerned with all levels of education. It will help to coordinate the work of the various joint committees of the Royal Society concerned with education, and will also look at specific problems itself.

Such a committee seems to be a logical development of the Royal Society's greatly expanded activities in education during the past few years. It already has joint committees with the Royal Institute of Chemistry, the Institute of Biology and the Institute of Physics, which are concerned with education in chemistry, biology and physics respectively. A joint committee of the Royal Society, the Council of Engineering Institutions and the Council of Science and Technology Institutes recently reported on the shortage of science and mathematics teachers in schools. Professor Butler said that the committee, which has met only once, has no specific problems under investigation as yet.

CONSERVATION

Environmental Revolution on Film

European Conservation Year has had a good week. While royalty and politicians were conferring in Strasbourg, Shell-Mex and BP Ltd was unveiling its contribution towards the education of the general public, a thirty minute colour film called *Environment in the Balance*, which had its premiere on February 11. This is the second film in a series on changing Britain and seeks to put the problems of today's environment in the context of Britain's history. The film modestly refrains from mentioning the battle against oil pollution. The figure, taken from the film, shows China clay spoil heaps in Cornwall.

IONOSPHERE

Omega off the Ground

from our Soviet Correspondent

On February 5, a new joint Franco-Soviet experiment was launched, designed to investigate near-space and the Earth's magnetic field, using a combination of drifting balloons and ground-level observations. This experiment, the first stage of the much publicized "Omega" project, is based on ground stations near Karpogor (Arkhangelsk province) in north Russia and the French base on the Kerguelen islands in the sub-antarctic Indian Ocean. Taking part in the experiments are specialists from the Soviet Institute of Terrestrial Magnetism, Ionosphere and Radio-waves, Institute of Terrestrial Physics, Polar Geophysical Institute, Leningrad and Gor'kii Universities and the French Centre National d'Études Spatiales, University of Toulouse (cosmic radiation centre), Centre National d'Études de Telecommunications, Institut d'Astrophysiques (Paris) and the Institut de Géophysique (Paris).

The programme of experiments calls for the launching of 37 high-altitude balloons, (27 French and 10 Russian) carrying loads of recording equipment of from 100 kg to 10 tonnes, over a period of 2 months. The polythene balloons themselves each weigh 250 kg.

The two stations lie at the ends of the same line of magnetic force, and by making simultaneous observations from both, it is hoped to investigate the variations of the radiation pattern in near space and the course of the entry of charged particles into the atmosphere. In particular, data are expected on the effect of the solar wind, and consequent magnetic storms, on the ionization of the upper atmosphere and the disruption of telegraphic and radio-telephone communications. It is hoped that these experiments will lead to practical improvements in spacecraft safety, and greater reliability of radio communications and navigation.

SOCIAL MEDICINE

Abortion Act in Action

THE Abortion Act is working better than either its opponents or its advocates hoped, according to a preliminary survey by P. Diggory, J. Peel and M. Potts (*Lancet*, i, 287; 1970). From the data for the first year and a half of its operation and estimates of the pattern of abortion over the past ten years, they conclude that the total of 65,000 legal abortions in England and Wales represents the continuation of a trend that has existed for at least a decade and that there has been no net increase in the number of abortions. There has instead been a switch from criminal abortions to therapeutic abortions under the National Health Service.

The act seems to have worked particularly well in ensuring minimum delays between seeking abortion and its performance; some 85 per cent of all terminations were carried out before the thirteenth week of pregnancy. Dr Peel believes that the proposed amendments to the act, which insist on the supervision by a doctor of consultant status, would inevitably increase the delays.

The abortion rate in Britain has been rising steadily from 6,000 in the first quarter since the act was implemented in April 1968 to 16,000 in the last quarter of 1969, but the rate of increase now seems to be levelling off. An encouraging sign is that the proportion of terminations carried out under the National Health Service has increased from 60 per cent of the total in the first quarter to 65 per cent in the final quarter. The regional discrepancies in the availability of National Health abortions also seem to be narrowing. In Sheffield, for instance, the abortion rate in the first half of the second year was 80 per cent greater than in the first year. In Liverpool the increase was 70 per cent, and even in Birmingham, where many doctors are opposed to abortion, there was an increase of 50 per cent. By far the greater proportion of all the private abortions, however, are in the north-west London area.

The chief contention, that there has been no net increase in abortions, is difficult to support statistically because there are no reliable figures for the number of criminal abortions performed before the act was passed. To support their argument, the authors show that the estimated increase of 6,000 in the total number of National Health Service and private abortions during 1967 was accompanied by a decrease of 2,000 in the total number of admissions for spontaneous and criminal abortions. On the assumption that only a quarter to a fifth of criminal abortions are admitted to hospital, it seems likely that most of what would have been criminal abortions were transferred to the private sector. Evidence for the rising trend in abortions in the years before the act comes from the increase in the number of National Health Service terminations from 2,000 in 1961 to 10,000 in 1967 and from Dr Diggory's estimates that the number of private therapeutic abortions has risen from 12,000 to 18,000 during the same period.

The act has been remarkably successful in reducing the death rate from abortion. The latest figures from the Ministry of Health show that in England and Wales the number of deaths from abortion, which has been between 45 and 50 per year for the past twenty or so years, dropped to 22 during 1969. It is estimated that, of these, three were due to private legal abortions, ten to National Health abortions and the remaining nine to criminal abortions.

Although the number of deaths from abortion is quite low, there is an urgent need for more research into the best techniques for abortion and into possible long term complications of the operation. But the chief point to emerge from the report is the need to improve contraceptive services. The survey has shown that "many women who have knowledge of and access to contraception fail to use it and yet are dismayed by the resultant pregnancy. . . . Diggory's series of 1,000 abortions included 18 women doctors, 99 nurses, 84 students and 29 teachers". Furthermore, the provisions of the 1967 Family Planning Act for contraceptive advice to be given to the unmarried have been fully implemented by only 39 out of 250 local authorities.

CONSERVATION

Environmental Postgraduates

HERIOT-WATT University has made a positive response to the growing interest in the environment. It has set up a one year postgraduate course leading to an MSc degree in environmental conservation. The course, which will be under the control of the joint department of architecture of Heriot-Watt and Edinburgh School of Art, aims to provide a study of the techniques involved in physical preservation, together with an interdisciplinary approach to the planned integration of existing buildings, sites and town areas, with new developments. Mr Peter Whitson, the director of the course, said that it will concentrate on "the conservation of areas, keeping what is good in the traditional, but relating it to the modern demands of traffic management, local government, law, finance and sociological implications".

Subjects studied will include the theory and practice of environmental conservation, together with its history and planning, and students will also look at the technology of conservation. The course will start next October, and it will take students with good honours degrees, preferably in architecture, town planning, landscape, building and social studies.

Parliament in Britain

Student Costs

Mr Gerald Fowler, Minister of State, Department of Education and Science, said that the cost per student in British universities was £1,408 in 1968–69, compared with £1,317 in 1964–65. The equivalent figures for students in colleges of education are £885 and £821 respectively. Mr Fowler pointed out that much of the capital expenditure included in these calculations is intended to provide for future expansion, not for present numbers. (Written answers, February 5.)

Ice Pollution

The British Antarctic Survey, a component body of the Natural Environment Research Council, will undertake a study of the Antarctic ice sheet later this year. Announcing this, Mr Fowler said that ice will be sampled at various depths, to provide a history of atmospheric precipitation over the last thousand years. The study should also indicate the extent of global pollution by long-lived substances. Results are not expected until 1971. (Written answers, February 3.)

Carbon Fibres and Lasers

Mr John Morris, Minister of Defence for Equipment, said that the possible use of carbon fibres in fighting vehicles is being investigated by government research establishments and by industry. It seems, however, that except for specialized applications, carbon fibre material offers no advantage over conventional materials, and their use is therefore not justified. Mr Frank Hooley, who had asked what studies the government is making on carbon fibres for defence purposes, also asked the Secretary of State for Defence to publish a White Paper on the military applications of laser technology. Mr Morris said, however, that, although defence research takes full account of laser technology, it would be inappropriate to publish the details. (Written answer, February 4.)

Computers

More than 5,200 computers are in use in the UK, and Britain ranks roughly on a par with the Federal Republic of Germany and Japan in computer usage. This estimate was given by Lord Delacourt-Smith, Minister of State, Ministry of Technology, and he added that manufacture of computers in the UK has increased by 24 per cent since 1966, while computer exports have increased by 20 per cent. In the year ended September 30, 1969, the total value of computers made in Britain was £143 million, and total exports were more than £55 million. (Oral answers, Lords, February 3.)

University Places

Mr Gerald Fowler said that he could not agree with the suggestion put by Mr Christopher Ward that thirty new universities must be built in addition to the expansion of existing institutions, in order to accommodate students in 1980. He said that there is considerable room for expansion in many existing institutions of higher education, and no decisions have yet been taken about providing new institutions. Mr Fowler strongly denied any intention to push up entry standards for higher education as the demand for places increases. (Oral answers, February 5.)

Miscellaneous Intelligence

Some 2,200 works on cancer are published yearly in 30 languages, according to the *Annual of Czechoslovak Medical Literature*, which makes no apology for contributing to the proliferative growth. The annual was compiled "in the memorable year 1968 which marked" —how could anyone forget it?—"the fiftieth anniversary of the independent state of Czechs and Slovaks. This year intensified our belief in the value of the individuality of small nations among other nations, well grounded in every branch of culture and science. We must, and wish to, compensate for our inadequate material forces by our spiritual strength".

Glomar Challenger, the research vessel sponsored by the JOIDES consortium of American oceanographic institutions, has steamed nearly 50,000 miles since the project began in August 1968 and has recovered four miles of oceanic sediment from 149 holes drilled at 84 sites in the Gulf of Mexico, Caribbean, Atlantic and Pacific. Core samples are available for study by any qualified scientists in the world.

The consumption of spaghetti immediately after hard physical exercise increases muscular efficiency threefold. This remarkable finding is reported in the organ of the health service of the Italian army, *Giornale di Medicina Militare*, **3**, 273; 1969.

The hazards of independent discovery are not confined to the scientific world. This month the Amsterdam publishing company of Elsevier has launched a new journal called the *International Journal of Bio-Medical Computing*, while from across the street the North-Holland Publishing Company has simultaneously issued the first number of a journal entitled *Computer Programs in Biomedicine*. The most pressing task of the new journals will doubtless be to compute each other's circulation.

The world that faced with equanimity the late Dr Philip Blaiberg's book *Looking at My Heart* is to be burst upon in April by Dr Christian Barnard's side of the story, which will tell of his "deeply religious conviction that it is his destiny to save human life". To help convey the message Dr Barnard has enlisted as co-author Mr Curtis Bill Pepper, whose previous works include *The Pope's Back Yard* and *An Artist and the Pope*.

The Wattle Research Institute of the University of Natal, South Africa, has clearly established that the Brown Mirid (formerly known as the Brown Jassid) wreaks more havoc in wattle than does the Large Green Wattle Cicadellid (formerly known as the Large Green Wattle Jassid). Wattle is also prone to attacks from the ballooning Wattle Bagworm, the Wattle Emperor Moth, the Large Wattle Chafer, the Wattle Looper and the Small Wattle Lappet Moth. What'll whittle the wattle away next?

It is little wonder that the Society of Cosmetic Chemists of Great Britain is buoyed up with joyous expectation because at its last meeting "the speaker finished by giving hope for the future indicating that the study of coalescence rates for the different droplets by measuring change in particle size distributed in time offered promising scope for further research".

•

NEW WORLD

Marking Time for 1971

THE United States budget for the fiscal year beginning this July is a spartan document, and there is nothing in it to suggest that the Federal Government is about to lift research and development off the plateau on which they have languished for the past several years. In the year ahead, the gains are neatly balanced by the losses, but the continuing pressure of the purse seems also to be forcing many of the Federal agencies to spend more of what they can spare for research and development on their own domestic activities. In the circumstances, the universities are probably lucky to have fared no worse than is promised for 1971. Another consolation, for the philosophically minded, at least, is that the latest budget provides an even better picture than its predecessors of how the Federal Government is proposing to manage its affairs.

In the coming year, combined federal expenditure on research and development is reckoned actually to fall from $15,192 million in the current fiscal year to $14,981 million in 1971. A small increase of $124 million in the cost of research supported by the government will be more than offset by a decrease in the cost of federally supported development, chiefly because of the money that will be saved by the attenuation of the NASA programme of manned space flight. Spending on academic research will, however, increase by about 1·6 per cent to a total of $1,475 million in 1971. The small decreases in the expenditure of the mission oriented agencies will be more than offset by increases in the amounts of money to be spent by agencies such as the National Science Foundation—at least if Congress eventually lets the Administration have its way. (See Table 1.)

Table 1. FEDERAL SUPPORT FOR ACADEMIC RESEARCH AND DEVELOPMENT (MILLIONS OF DOLLARS)

	1969 (actual)	1970 (estimated)	1971 (estimated)
Health, Education and Welfare	604	641	653
National Science Foundation	219	213	230
Defense	243	225	224
AEC	101	100	97
NASA	144	131	105
Agriculture	61	69	80
Other	56	70	88
	1,426	1,449	1,475

Military research and development is, however, unlikely to find sufficiently powerful friends to reverse the decline expected in the coming year, from $7,910 million in the current year to $7,763 million in 1971. The chief causes are the declining expenditure on development programmes for the F111 aircraft (in both its versions), the Poseidon missile and the newer versions of the Minuteman. On the other hand, more money is being spent on the new F15 fighter, antiballistic missiles and a variety of tactical aircraft projects. Laboratories such as those at the Wright–Patterson Air Force Base will grow. The Department of Defense will, however, save a substantial amount of money—the cancellation of the Air Force plan for a Manned Orbiting Laboratory has made possible a reduction of expenditure to an estimated $480 million in the coming fiscal year for military research and development in "astronautics and related equipment". This chimes in well with the general trend of expenditure on military defence, which is expected actually to decrease to nearly $6,000 million in the coming year, and which accounts for only 36·7 per cent of the budget for the coming year, compared with nearly 50 per cent in 1960.

The continuing decline of NASA expenditure is one of the most conspicuous features of the budget for 1971, as is the way in which NASA has given up its hopes for a continuing programme of journeys to the Moon. Between the current fiscal year and 1971, the expenditure of NASA as a whole will fall from $3,110 million to $2,606 million. Most of the reduction will be accounted for by the stretching out of the programme of landings on the Moon, but NASA is also hoping to save a great deal by the attenuation of the biological research programmes (down to $12·9 million in 1971).

The programme of fiscal and astronomical research is, however, sustained. In 1971, NASA plans to spend $127·6 million on physics and astronomy and $165·1 million on exploration of the planets. This represents a reduction of less than $2 million on the year. By contrast, expenditure on the support of the university research by means of training grants for graduate studies is being brought entirely to a halt.

The budget statement says that a great deal of hope rests on the development of rockets which can shuttle to and from orbits above the Earth—during 1971, the basic work on the design of such a vehicle should be complete. There is also continuing interest in the nuclear rocket motor from which it is hoped to attain about 75 thousand pounds of thrust for long distance journeys. In the distribution of research money, the NASA laboratories at most places except Cambridge, Massachusetts, where the Electronics Research Center has recently been closed, will share in what seems to be a general 2 per cent increase in expenditure.

But medical research under the aegis of the Department of Health, Education and Welfare is one of the few fields of scientific research which will benefit substantially from the budget—it is expected that the total expenditure in 1971 will be increased by close on $200 million to a total of $1,459 million in 1971. The total amount of Federal support for health research amounts to $1,660 million, provided by thirteen agencies of which the Department of Health, Education and Welfare accounts for 73 per cent. The budget says that expenditure is being channelled deliberately towards fields such as "research on viruses implicated as the cause of cancer", heart disease, dental caries, contraceptives, drug abuse and alcoholism. The other agencies of the Federal Government are also supposed to contribute—NASA is helping with "the control of noise pollution from aircraft and the use of aerial and satellite mapping of sources of pollution, erosion and other ecological problems".

The National Institutes of Health do well out of the 1971 budget. The total expenditure will amount to $1·526 million in 1971, an increase of 4 per cent, and the money available for grants and fellowships will increase from $706 million in the current year to $723 million in 1971. There will, however, be a small reduction in the cost of support for medical education, from $469 million to $454 million. The National Cancer Institute (which will receive an extra 16 per cent in 1971) is said now to have the "aim of developing a vaccine for preventing virus induced cancers". Most of the extra money will be spent internally.

The National Institute of Dental Research also has 12 per cent extra to spend ($34 million) as does the National Heart and Lung Institute ($171·7 million). By contrast, the National Institute of Allergy and Infectious Disease is on a declining budget—$99·2 million in 1971.

The National Science Foundation, the perennial Cinderella, may have better luck this year than in the past. The Administration is asking for an extra $73 million, although it seems clear that most of this is destined for extra work in the environmental sciences. The National Science Foundation should have rather more than $511 million to spend in the coming year but the increase of its expenditure in research will be from $317 million in 1970 to $384 million in 1971. The budget statement says that the increase is deliberately intended to give "support to research in areas where new scientific understanding is needed to aid in the solution of pressing problems affecting mankind" and it goes on to mention the environment, oceanography, ecological systems "and other problems of our society".

Specifically, the Foundation will spend more on its Arctic Research Program, its Earthquake Engineering Program and what is called the International Decade of Ocean Exploration. The Foundation is also planning to spend more on the International Biological Program.

The extra funds in the budget for the support of research should, the calculation goes, make it possible to award 4,305 grants in the coming year—the greatest number in the Foundation's history. But the Foundation is also planning to increase its investment in national research centres—the improvement of the 1,000 foot radio telescope at Arecibo will cost $3·8 million, for example—and it is clearly willing to go some way to meet the case made by the National Science Board for a new basis for supporting academic science by spending $55 million on institutional support.

The Atomic Energy Commission has managed to keep its research and development at a more or less constant level in spite of the decline which there has been in its total budget over the years. Roughly 18 per cent of its total budget on research and development will be spent in 1971. The Nuclear Weapons Program still remains a large part of the AEC's programme. In 1971, the Commission's expenditure on development of civil nuclear power stations will decline from $221 million to $149 million, chiefly a recognition of the extent to which the electrical companies are taking over this work. Basic research will cost the Commission $488 million—a decline of $14 million a year. What seems to have happened is that the AEC has been able to shoulder the continuing cost of the 200 GeV accelerator by shutting down similar facilities elsewhere. The most spectacular change, however, in what the Commission proposes is a reduction in the cost of the Plowshare Program from $14 million to $8 million—evidently the first results of the evaluation programmes leave a lot to be desired.

DESERT RESEARCH

National Science Foundation Grant

The International Biological Program has stimulated the National Science Foundation to give $654,000 to the Utah State University at Logan for a programme of research on desert ecology. The intention is that the Utah centre should serve as a place for a large group of biologists and others drawn from universities in the Western states. To begin with, the money will be spent on field studies in a valley on the border between Utah and Idaho, on a site near Tucson, Arizona, and another in New Mexico. The objective of the research programme includes a study of the relationship between human beings and desert conditions, and it is intended that other sites will be chosen for the experimental work once the programme is under way. With conservation very much in the air, the National Science Foundation says that there is a danger that deserts can be "easily destroyed", partly by the rapid growth of population, so that there is an urgent need of research programmes.

The immediate programme will consist of a co-ordinated network of field studies linked with computer modulators of them and followed by specific attempts to check the prediction of the computer models against real life. There will be particular interest in the rates of growth of desert plants and of the relationships of water and nutrients to the plants. There will be a special investigation of photosynthesis in desert conditions especially in its relationship to flowering, and there will also be a systematic study of the life span of desert animals.

The validation studies which form a part of the programme are in many ways its most novel feature. A part of the work involved will be a careful inventory of the biological environment at each of the three sites to be investigated so as to provide a starting point for later studies. One project will involve the fixing of small radio transmitters to various wild mammals and two radio towers will be built to collect information from this equipment.

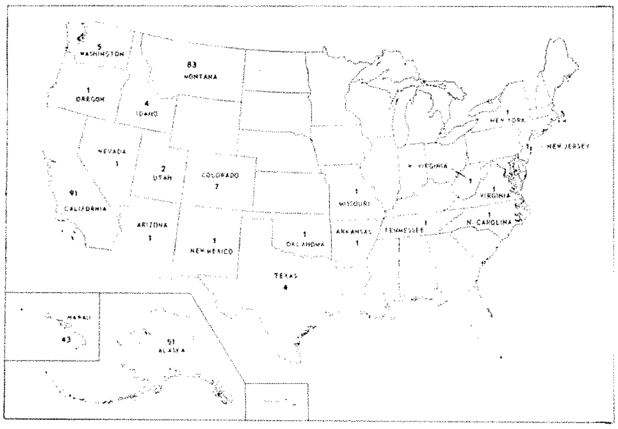
EARTHQUAKES

The American Toll

from our Geomagnetism Correspondent

During the past hundred years, earthquakes in the United States have killed more than 1,500 people and caused damage costing more than $1,300 million. North America continues to be earthquake prone; but the National Earthquake Information Center at Rockville, Maryland, reports that 1969 was the fourth successive year without fatalities. The most recent deaths (seven) resulted from a tremor in Seattle, Washington, in 1965.

Last year 303 epicentres of earthquakes strong enough to be felt or cause damage were detected in



Earthquake map of the United States for 1969.

twenty-two states, although seismographs recorded many thousands of minor shocks. Top of the league table was California (ninety-one), followed by Montana (eighty-three) and Alaska (fifty-one). It is unusual for Montana to feature so high—the last really serious tremor there occurred in 1959 at Hebgen Lake when twenty-eight people died. Normally Alaska and California fight for top place, although because of the sparse population in Alaska it is probable that many earthquakes are not recorded. The most severe tremor last year caused six million dollars' worth of damage in Santa Rosa, California, where two shocks occurred within 85 minutes, injuring several people. Both of these earthquakes were felt along the west coast from Clear Lake to San José and shook large buildings in San Francisco.

Elsewhere in the world, the worst earthquake killed 136 Peruvians in October. Reports of 3,000 deaths by an earthquake in China last July have not been confirmed. Other fatal earthquakes in 1969 included those in the Celebes Islands (sixty-four killed), Iran (fifty), Ethiopia (twenty-four), Yugoslavia (twenty), Morocco-Portugal (thirteen), South Africa (eleven), Turkey (eleven), Egypt (two) and Albania (one).

SUN

America in Eclipse

by our Astronomy Correspondent

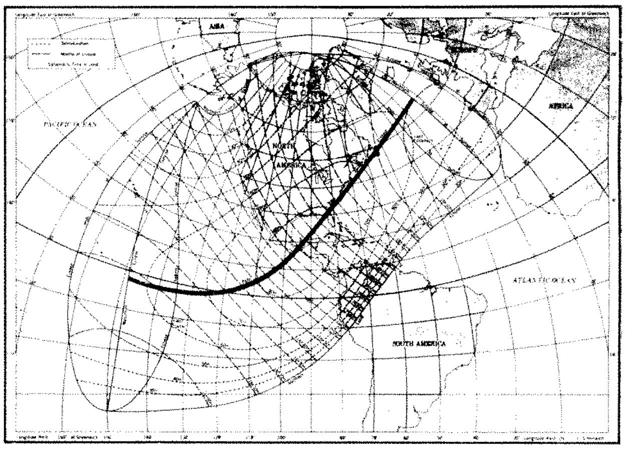
THE next astronomy spectacular is the total eclipse of the Sun on Saturday, March 7. As the accompanying eclipse map from *The American Ephemeris and Nautical Almanac* shows, the partial eclipse will be visible over all of central and north America with the exception of parts of Alaska and Greenland, but the total eclipse is limited to a roughly 100-mile wide band which sweeps across Mexico, Georgia and the Carolinas, and grazes the east coast of the United States and Canada.

Readers planning to be on the east coast next month would do well to arrange their itinerary around the eclipse, the first since 1963 to touch the continental United States. All the details are in the circular published by the US Naval Observatory—the eclipse observer's bible—in this case circular No. 125. In the United States the best locations are in Florida, the Carolinas and Virginia, where the climatological data show that there is a 40 per cent chance of seeing the eclipse. Farther north the conditions deteriorate, and Nantucket Island, which is on the path, is not a recommended site. In Nova Scotia and Newfoundland the chances that March 7 will be a clear day are small: Shearwater, NS, is probably best with a 26 per cent probability of a clear day, but at Gander Airport, just off the path of totality, the probability is down to 19 per cent.

	Time of mid-eclipse	Percentage of totality
Albany, NY	13.43 EST	92
Boston, Mass.	13.46 EST	96
Chicago, Ill.	12.25 CST	72
Columbus, Ohio	13.30 EST	83
Dallas, Tex.	12.00 CST	71
Denver, Col.	10.57 MST	46
Halifax, N.S.	14.55 AST	100
Kansas City, Mo.	12.12 CST	64
Los Angeles, Cal.	9.26 PST	36
New York City	13.42 EST	96
San Francisco, Cal.	9.26 PST	27
Tucson, Ariz.	10.34 MST	48
Washington, DC	13.37 EST	95

But devotees will be going to Mexico—not to Minatitlan where the eclipse path crosses the north coast and which has a weather record inferior to the southern United States, but to Oaxaca de Juarez where cloudiness is low because of the elevation of more than 5,000 feet, or to Salina Cruz on the south coast. The magazine *Sky and Telescope* has prepared a guide to eclipse sites in Mexico together with useful hints (stock up on supplies, including canned and prepared foods, and especially bottled water and drinks; your physician may suggest additions to your medical kit), as well as a list of sites which have been set aside for observers in the United States.

The table lists the times of mid-eclipse and the percentage of totality for several locations in north America.



NEWS AND VIEWS

One Way for Neutron Stars to Pulse

ALMOST everybody agrees that the mechanics that keep pulsars ticking away must be the rotation of neutron stars—the range of periodicities which have been recorded sees to that—but the question of why neutron stars should emit radiation in such quantities is still as wide open as ever. With well over forty pulsars now listed, there is an embarrassment of observational detail to explain. Two pulsars have aroused most interest, NP 0532 in the Crab Nebula supernova remnant and PSR 0833–45 which is believed to be associated with the suspected supernova remnant Vela X. Both are famous for their rapid periodicities of 30 and 10 pulses per second respectively and for the surprising irregularities which they have shown in their pulsations, and it is through the irregularities that the Crab and Vela pulsars are believed to hold the key to the structure of neutron stars. But an understanding of the emission mechanism is more likely to come from a distillation of the features of the radio signals from all forty or so pulsars.

There is a lot to account for, and the value of the article by M. M. Komesaroff (of CSIRO) on page 612 is that it is a hypothesis against which future observations will be measured. The basis is the oblique rotator model which has it that the magnetic axis of the spinning neutron star is at a large angle of tens of degrees to the rotation axis. Komesaroff gives reasons why the radiation should be emitted in a hollow conical beam which is coaxial with the axis of the dipole magnetic field. The spin of the neutron star sweeps the narrow beam around, and depending on how the beam crosses the observer the double-pulse structure of some pulsars and the single-pulse structure of others can be synthesized.

Any theory, of course, has to account for the intensity of the radio emission, and this involves large numbers of particles radiating in phase. According to Komesaroff, most of the radiation comes from particles within a few radii of the surface moving along lines of magnetic field near the magnetic pole. The radiation, however, is not the ubiquitous synchrotron radiation of particles gyrating around field lines, but rather arises simply from the acceleration of particles which describe a curved path, in this case relativistic particles in a field of something like 10^{12} Gauss.

As such, the model of Komesaroff is a crystallization of two ideas—the notion that a narrow beam could be obtained if the radiation comes from near the magnetic pole (Radhakrishnan and Cooke) and the notion that the radiation could be from the curved paths of particles along field lines rather than from synchrotron radiation (Radhakrishnan).

Despite the impressive list of features of the radio pulses which Komesaroff has accounted for, nobody is going to say that this is the answer. For one thing, the model does not account for everything, although this is hardly surprising. For another, not enough is said in the article about the polarization of the signals which most people suspect must hold the key to the emission mechanism. But what Komesaroff has succeeded in doing is to set up a feasible Aunt Sally against which the measurements can be matched, and the outcome should be a better realization of what properties the ultimate model should have.

What Sigma Factor Does

UNTIL last year it was far from clear how the enzyme RNA polymerase recognizes the sites on DNA where transcription is to be initiated. But then Burgess *et al.* reported fractionation on phosphocellulose columns of the RNA polymerase from *E. coli* into a "core enzyme" and a "sigma factor" (*Nature*, **221**, 43; 1969). The former comprises protein of four subunits with a combined molecular weight of about 400,000, and the latter a single polypeptide chain of molecular weight about 95,000. The core enzyme retains the ability to catalyse the synthesis of RNA chains under direction from a DNA template *in vitro*, quite efficiently when alien calf thymus DNA is provided as template but with a great reduction in activity when the DNA comes from its usual source, *E. coli* or phage T4. But in the latter case the addition of sigma factor restores the synthetic activity of the core enzyme, and later work (see, for example, *Nature*, **222**, 537; 1969) showed that the factor acts on the initiation of RNA synthesis. It associates with the core enzyme to yield a "complete enzyme" complex, which then binds to the DNA template; once the synthesis of RNA by the core enzyme is under way, the sigma factor is released from the transcription complex, and can be used again to initiate transcription by another molecule of core enzyme.

An obvious possible use of this mechanism is for selecting the genes at which transcription is to take place. Indeed, Bautz *et al.* have shown (*Nature*, **223**, 1022; 1969) that the sigma factor may play such a part when *E. coli* cells are infected by phage T4. An analysis of the RNA synthesized *in vitro* on T4 templates showed that addition of the sigma factor specifically stimulates the core enzyme into transcribing those genes of the phage which are usually expressed *in vivo* during the first minute after infection. In the absence of factor, RNA chains are initiated at random sites along the whole T4 DNA molecule.

On page 598 of this issue of *Nature*, Sugiura, Okamoto and Takanami report the latest development in the story of how the sigma factor exerts its selective control over transcription. They used the double stranded form of bacteriophage *fd* to direct the synthesis of RNA *in vitro* by core enzyme, both in the absence and presence of sigma factor. Phage *fd* consists of a single strand of DNA which is converted to a duplex replicating form (RF–DNA) when infecting its hosts.

Sugiura *et al.* found significant differences in the nature of the RNA species synthesized when the core enzyme is complemented by the addition of sigma factor to the incubation medium. RNA chains in *E. coli* begin predominantly with purine nucleoside triphosphate, largely comprising the species pppGpPyp. . . and pppApPyp. . . When the core enzyme alone was used to achieve synthesis, less than half the termini of the RNA species synthesized were in this category. Addition of sigma factor stimulated RNA synthesis, so that more than 70 per cent of chains began with the expected sequences. Sedimentation analysis of the RNA products showed that species of a definite size (about 26S) tend to be synthesized by complete enzyme, but there is a much greater spread of size distribution when sigma factor is absent. The RNA synthesized by the complete enzyme can hybridize only with denatured RF–DNA, that is, it is complementary to only the minus strand. By contrast, the RNA synthesized by core enzyme can hybridize both with denatured RF–DNA and with the single-stranded DNA from mature phages. About twice the amount of hybridization takes place with the denatured DNA species as with the mature phages.

It seems, therefore, that in the absence of the sigma factor the core enzyme is free to initiate RNA synthesis at random points along either strand of the DNA template; this results in the production of species with unusual 5′ terminal sequences, of a more dispersed size distribution, and which can hybridize with either strand of the phage DNA. The effect of the sigma factor is to restrict the catalytic activities of RNA polymerase, so that it transcribes only the minus strand of the template from certain starting points. These presumably correspond to the sites at which transcription is initiated *in vivo*.

POLYMERASES

Multifarious Molecules

from our Molecular Biology Correspondent

THE DNA-dependent polymerases are highly specialized enzymes, with various functional modes. RNA polymerase must be able first to recognize and attach to the initiation site on the DNA template, then to take up the appropriate nucleoside triphosphate, to initiate the chain, to catalyse chain propagation and finally to liberate the RNA when synthesis is complete. The initiation and termination steps are now known to involve protein factors, the first of which is in effect a subunit of the enzyme, as isolated.

The uncoupling of various of the functional modes of RNA polymerase by chemical modification is described in an interesting study by Ishihara and Hurwitz (*J. Biol. Chem.*, **244**, 6680; 1969). They establish that any of the four common nucleoside triphosphates will bind to the polymerase in the absence of the template, though the number of binding sites is still uncertain: Ishihara and Hurwitz obtain conflicting results by two different experimental procedures. When DNA is present, there is strong preference for the attachment of CTP or GTP, which accords with the known composition of the initiation sites and means that the DNA is able to control the affinity for different substrates. In addition, in the presence of DNA the bound triphosphate will exchange against labelled pyrophosphate, which may well reflect the formation of a phosphodiester bond, and is probably therefore a measure of the polymerase activity of the enzyme.

Chemical modification produces striking results. Treatment with specific reagents for thiol groups leads to loss of activity, but the ability to bind the triphosphates in the absence of DNA was scarcely impaired. The capacity to interact with the template was entirely lost. The contrary is found when the enzyme is exposed to reagents specific for amino groups: the binding of RNA is unaffected, but there is no longer any interaction with the triphosphates. Finally, after treatment with a reagent largely specific for histidine, or photo-oxidation in circumstances most likely to lead to destruction of histidine, the enzyme is again inactivated, this time, however, with retention of the ability to bind both DNA and substrates; the exchange reaction against pyrophosphate is completely inhibited, however, and this may cautiously be interpreted to signify failure of the polymerization function. Only with thiol reagents is there any detectable physical change: a fragment sedimenting at 2S is released, which it would be agreeable to be able to equate with the σ (initiation) factor; this is still uncertain, however, and indeed the σ factor has been reported to sediment at 4–5S (though it may itself, of course, be prone to dissociation by thiol reagents). Differential sensitivity of the several functions to thermal denaturation has also been observed. A different effect again is produced by the antibiotic, rifampicin, which blocks initiation of the RNA chain, but fails to interrupt propagation if initiation has already been allowed to happen (Maitra and Barash, *Proc. US Nat. Acad. Sci.*, **64**, 779; 1969). There seems good reason to hope that the operation of this key enzyme will soon be understood in some detail.

DNA polymerase (or, as it should perhaps be called in the prevailing atmosphere of retrenchment, repair enzyme) is also a multifarious protein. It is reported to consist of a single chain with the unusually high molecular weight of 109,000, and it catalyses DNA synthesis, pyrophosphate exchange against the bound triphosphates, and two modes of exonucleolytic degradation, from the 3′ and 5′ ends. Klenow and Overgaard-Hansen (*FEBS Lett.*, **6**, 25; 1970) have treated the enzyme with a protease, subtilisin. When DNA is absent, this causes loss of exonuclease, but not of polymerase activity. When DNA is present, both activities remain substantially intact, but fractionation by gel filtration reveals the presence of two fragments, one possessed only of polymerase, the other only of nuclease activity. The molecular weights, as estimated from the elution positions, are respectively some 70,000 and 35,000. The inference is that DNA polymerase consists of two parts, joined perhaps by only a single exposed loop of polypeptide chain, that can be cleaved without other damage to either half of the molecule. This evidently is a case in which two different functional subunits are tethered together. The advantage to the cell of this arrangement is not at this stage clear.

INVERTEBRATES

Worms on Ice

ALTHOUGH ice worms (*Mesenchytraeus solifugus*) have been reported from Alaska, Yukon Territory, British Columbia and Washington State, few have been seen alive in their natural habitat by zoologists. Dr M. Tynen of the University of Alberta has recently found some in the ice of the Cliffe Glacier in Central Vancouver Island and on the Snow Dome of Mount Olympus, Washington State.

Ice worms in the snow of the Cliffe Glacier, Vancouver Island.

During the day, ice worms, which are black and about three quarters of an inch long, were found clumped together 6–12 inches deep under the drainage furrows of the névé. Although they were in hard crystalline ice, which could only be removed with the aid of an ice axe, the worms seemed to move with considerable ease. Tynen thinks that they may have crawled along the crystal boundaries. At dusk, the worms rose to the surface and started to disperse from the drainage furrows into the mounds between. They all disappeared, however, as the Sun rose. This nocturnal activity has been noted before.

The worms probably feed on the "redsnow" algae (*Chlamydomonas nivalis*) which collect in the drainage furrows together with windblown dust and other debris. The furrows seem to be self perpetuating: they tend to collect dust which imparts a darker colour to their surface, and this in turn results in increased ablation. The growth of the algae may be enhanced by mineral nutrients present in the dust, made mobile by rapidly melting ice. The drainage furrows could also trap windblown organic particles, such as pollen grains, which would be another possible source of food for the worms.

If the worms feed on algae and pollen grains, there is, of course, the question of how they digest cellulose. Many of those found had large ciliates in the fore-part of the gut, and these may have been symbionts that digest cellulose. Their occurrence, however, is by no means universal in ice worms, and they have not been noted before. Possibly, the mineral particles which are ingested, and can be seen in serial sections of the worm, act with the movements of the gut to triturate the food and break down cellulose.

The Cliffe Glacier, like all those in which ice worms have been recorded, is temperate, so that during the summer its temperature is never below 0° C. In winter the surface may be covered with 20–30 feet of insulating snow, so that the level where the worms live probably maintains a temperature at or very near the freezing point of water. Worms held in the hand with a piece of ice became very agitated as the ice melted, but Tynen thinks that this may have been a response as much to the change in consistency as to any increase in temperature.

Samples of the ice worm population of the Cliffe Glacier collected at the end of July contained a large proportion of immature individuals. It is not possible, however, to do more than speculate as to the pattern of the annual life cycle, for samples were not collected at other times of the year. There seems to be no reason why the worms could not feed throughout the winter on the resting stages of the snow algae, trapped with them under the winter snowfall. The immature individuals observed in July would then be mature by the following spring.

BACTERIA

The Stuff of Cell Walls

from our Microbiology Correspondent

MICROBIOLOGISTS are finding that changes in the chemical and physical environments can induce profound changes in microbial cell walls. Schleifer, for example, has noticed that changes in the nature and amount of the amino-acid complement of culture media can affect the type of substitution on the L-lysyl residues and the extent of interpeptide linkage in the walls of staphylococci (*J. Gen. Microbiol.*, **57**, xiv; 1969). Such modifications may be crucial in determining the susceptibility or resistance of bacteria to lytic enzymes.

Ellwood and Tempest did pioneering work when they described modifications in the anionic polysaccharide content of the walls of *Bacillus* which are dependent on magnesium and phosphate. Recently they obtained similar results with Gram positive cocci (*J. Gen. Microbiol.*, **57**, xv; 1969). And Garrett found that when *Bacillus subtilis* is starved of magnesium, not only is teichoic acid synthesized in the cell wall, but the synthesis of peptidoglycan is inhibited (*Biochem. J.*, **115**, 419; 1969). The likely explanation for this is that the protoplasmic membrane loses some of its structural and functional integrity when magnesium is lacking, and that the activity of membrane-bound peptidoglycan synthetases is precluded.

Peptidoglycan, which comprises about 5–10 per cent of the wall of Gram negative bacteria, and up to 80 per cent of the wall of Gram positive organisms, has been thought to be chiefly responsible for the mechanical strength and morphology of the cells. Rogers and his colleagues, for example, found an increase in the degree of cross-linking in peptidoglycan when certain mutants of *Bacillus subtilis* were converted from the spherical to the rod form by supplementing the medium with certain amino-acids (*Nature*, **219**, 285; 1968).

Two configurational models have been constructed for the peptidoglycan of *Staphylococcus aureus* in which the polysaccharide chains are aligned head to tail and are hydrogen bonded together (Kelemen and Rogers, *J. Gen. Microbiol.*, **57**, xiii; 1969). An α-helical model accorded little hydrogen bonding, but a β-configuration in the form of a pleated sheet possessed *trans* carboxyl groups which accommodated a regular net-like organization of the peptidoglycan in which 60 per cent of the amino groups participated in hydrogen bonds.

Although acknowledging that peptidoglycan is essential in determining cell morphology, Braun and Shwarz (*J. Gen. Microbiol.*, **57**, iii; 1969) argue that this function is a reflexion of its association with other cell wall components. They have analysed the interaction between peptidoglycan and lipoprotein in *Escherichia coli* and proposed a model in which about 10^5 lipoprotein molecules are distributed regularly over the surface of the peptidoglycan. One lipoprotein moiety appears to be associated with every tenth repeating unit of the peptidoglycan and is linked by an N-terminal lysine to the carboxyl group of diaminopimelic acid residues. Under the microscope, cell walls treated with trypsin were seen to be split into two layers. This, coupled with a rapid decrease in the optical density of the treated material, suggested to Braun and Shwarz that lipoprotein, too, plays a significant part in stabilizing the cell wall.

VIROLOGY

Fusion Within and Without

from our Cell Biology Correspondent

In the past five years the use of inactivated para-influenza viruses to effect the fusion of somatic cells into viable hybrids has emerged as a powerful biological tool. The technique has already transformed somatic cell genetics from the emeritus professor's pipe dream to a rapidly expanding experimental discipline; it is also increasingly being applied in virology and viral oncology, for example in promoting infection of refractory cells with such viruses as polio and polyoma, and no doubt there are many more applications to come. Most of the credit for this innovation belongs, of course, to Henry Harris and his collaborators at Oxford; it was they who realized (*Nature*, **205**, 640; 1965) the potential for cell biology of Okada's discovery (*Exp. Cell Res.*, **26**, 98; 1962) that high multiplicities of Sendai virus induce cell fusion. But the way in which these viruses induce fusion remains obscure for perhaps the good reason that, for most people who use the technique, all that counts is that it works; how it works is of secondary importance. The mechanism of fusion is not, however, without its intrinsic interest and Bratt and Gallaher (*Proc. US Nat. Acad. Sci.*, **64**, 537; 1969) suggest that viral lipids or possibly lipoproteins are the fusion factor, at least in Newcastle disease virus (NDV).

While investigating the infection of secondary cultures of chick embryo cells with NDV they noticed that different strains of the virus vary in their ability to induce cell fusion; the strains seemed to fall into two classes, those which induce fusion directly and those which induce fusion only after the cells are infected and viral materials have been synthesized. Bratt and Gallaher call the two mechanisms fusion from without and fusion from within respectively. Fusion from without is a property of NDV–HP and NDV–EH strains; the fusion induced is as great 2·5 hours as 7 hours after virus has been added; it is independent of the *p*H of the cell's medium; it is greatest at the highest multiplicities of infection; and, most important of all, the virus does not have to be infectious to induce fusion.

Fusion from within by NDV–AV, on the other hand, requires at least 6 hours, is dependent on *p*H—there is most fusion at high *p*H—and the virus must be infectious. Inhibition of protein synthesis by cycloheximide either before or after infection has no effect on fusion from without by NDV–HP; fusion from within is inhibited by the drug if it is added early, but susceptibility decreases as addition is progressively delayed after infection. Both fusion processes are, however, completely suppressed by pretreatment of the virus with antiviral antibody. When antibody is added after infection, fusion from without becomes completely insensitive to inhibition between 20 and 40 minutes after infection even though fusion does not reach its maximum until 2 to 3 hours after infection. Fusion from within, on the other hand, remains completely susceptible to inhibition by antibody for 5·5 hours after infection.

Clearly Bratt and Gallaher have established that the two types of fusion are quite distinct. Fusion from without seems to result from the direct interaction of cell and virus, and the fact that it occurs at 38° C and 43° C but not at 23° C brings to mind two other temperature dependent interactions of cells with NDV virus-penetration and cell interference. Fusion from within, on the other hand, seems dependent on viral protein synthesis but not DNA-dependent RNA synthesis. The two types of fusion seem to be strain specific and, because the capacity to induce fusion is restricted to viruses with lipoprotein envelopes and because agents which alter these lipids are known to diminish fusion from without, Bratt and Gallaher suggest that either viral lipids or lipoproteins are the fusion factor. The fact that fusion from either within or without is strain specific and the lipid composition of NDV envelopes is also strain specific, of course, supports this notion.

CANCER

Oncogeny and Ontogeny

from a Correspondent

The considerable problem of defining the chemical events involved in carcinogenesis was tackled at the second meeting of the annual winter symposium of the Department of Biochemistry of the University of Miami and the Papanicolaou Cancer Research Institute in Miami on January 22 and 23 (see *Nature*, **225**, 498; 1970, for report of first meeting). One approach to this problem is to use a minimal deviation hepatic tumour, the Morris hepatoma, which in its well differentiated form differs from other experimental rodent tumours by its low glycolytic capability, high respiration and use of fatty acids as metabolic fuel. Many years of study of this hepatoma has led Professor Van R. Potter (Madison) to the concept that "oncogeny is blocked ontogeny".

Long term evolutionary changes in gene expression as seen in the amino-acid sequences of the same protein of many species have a counterpart in the relatively rapid change from the normal to the cancerous state. Dr S. Weinhouse (Philadelphia) concluded, after study of several glycolytic enzymes, that certain types of Morris hepatoma tumours produce a switch in genome readout involving the suppression of enzymes concerned with hepatic function and the unmasking of other enzymes normally suppressed in their tissues of origin. Dr M. Farber (Pittsburgh) spoke of a chemically induced "hyperplastic nodule" that is homogeneous, not normal, but not yet cancer, and which seems to be a "precursor"; from this relatively homogeneous cell population a heterogeneous mixed population of cancer cells evolves. These "precursor" cells have abnormal DNA and carbohydrate metabolism.

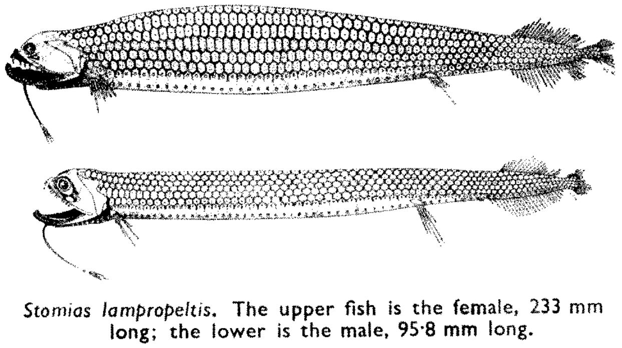
The homology and variations of the gamma globulins with respect to both primary structure, discussed by Professor R. R. Porter (Oxford), and tertiary structure, discussed by Dr F. W. Putnam (Bloomington), reflect the "fast evolution" of response to antigens with variations in structure, both primary and tertiary, which play a part in determining the antibodies formed, as Professor M. Sela (Rehovot) pointed out. The results of researches with substances of known structure, leading to exact chemical data, throw no more light on the origin of cancer than less exact studies. But Dr M. Potter (Bethesda), making use of myeloma protein synthesis, found that the precursors of neoplastic cells actively formed antibodies when they underwent neoplastic transformation.

Dr H. Busch (Houston) reported further evidence of a "cancer operon" as evidenced by the nature of the RNA found in the nucleolus of cancer cells. Finally, a way of studying the genome which controls the events leading to the replication of DNA, which precedes mitosis in cancer, was described by Dr R. Beserga (Temple, Philadelphia). He has used salivary glands taken from rats and then treated with the catecholamine isopreterenol.

ICHTHYOLOGY

New Name in Deep Waters

The fish in the illustration has been raised recently from subspecies to full species by Dr Robert H. Gibbs jun. of the Smithsonian Institution. This creature, which inhabits the deep waters, between 200 and 1,000 metres down, in the eastern tropical Pacific, was first included in the species *Stomias colubrinus* by Brauer in 1906, and in 1964 Blache decided that it was a subspecies and called it *Stomias colubrinus orientalis*. Gibbs, however, scorns this distinction, based on a statistical test of differences from specimens of *S. colubrinus* living in the south-eastern Atlantic. He is not prepared to accept differences between two nominal subspecies if they are so slight as to be unrecognizable from an inspection of specimens. But he has looked again at the two populations and found a much more impressive difference than Blache's variations in rays and photophores. The teeth and their arrangement are sufficiently different, according to Gibbs, to distinguish the eastern population as a separate species, *Stomias lampropeltis*, from the Atlantic population, which remains *Stomias colubrinus* (*Smithsonian Contributions to Zoology*, No. 31; 1969).



Stomias lampropeltis. The upper fish is the female, 233 mm long; the lower is the male, 95·8 mm long.

This piece of taxonomy is but one aspect of a study of the ten species and subspecies of *Stomias*, during which Gibbs was the first person to describe sexual dimorphism in this genus. The sexes differ principally in that males are smaller than females and tend to have larger eyes.

ARCHAEOLOGY

Signs of Early Man

The village of Swanscombe, on the banks of the River Thames in Kent, may in a year or two yield the first intact Lower Palaeolithic camp site to be found in Britain. Dr J. A. Waechter told members of the Royal Anthropological Institute on February that the first two seasons of excavations sponsored by the institute have proved more promising than pessimists expected, and have yielded what seems to be a refuse dump. If this is so it can only be a matter of time and careful excavation before a camp is found nearby.

Such a find would thoroughly vindicate everyone who has supported the project of excavating this site. It is of course best known for having yielded in 1935, 1936 and 1955, three bones which fitted together to make up the back of the skull of Swanscombe man, dating from the second interglacial period (200,000 to 350,000 years ago). Because the front of this skull was never found it has not been possible to say more than that this was a being very similar to *Homo sapiens*. Waechter feels that at least one of these men must have drowned himself in the lake that used to stand nearby, and have been preserved intact in the sediments. This would be a great find indeed.

When the present investigations began in 1968 the site, previously much dug for chalk and gravel but now protected by the Nature Conservancy, had been more or less cleared of the upper layers of gravel. These contained the typical flint hand axes of the Acheulian culture (which lasted from about 200,000 to 100,000 years ago). But the lower layers of loam and gravel, which had remained untouched since they were once covered by the still water of the lake, held promise of yielding material dating from the earlier Clactonian culture (probably 250,000 years old). This promise was fulfilled in 1968 and 1969. Throughout the lower loam Waechter and his team found Clactonian flints, which are more primitive than their Acheulian counterparts, some in mint condition. There were also considerable quantities of antlers, one complete set attached to the skull of a red deer. Other finds in the loam included elephant bones, the tooth of a rhinoceros and a complete skull of a bear. The gravel below yielded very little bone but many more implements than the loam.

The bone, which has proved difficult to handle because of its great fragility, is at present being identified, and will later be carefully examined for any evidence of human influence on it. One hopeful sign is an antler which seems to have been worked into a point, probably for use as a tool. Working on the assumption that he has found a refuse pit, Waechter enlisted a local band of small boys to emulate their Palaeolithic forebears and see how far they could effortlessly throw objects with the dimensions of his finds. Having concluded that about thirty yards was probably the limit for easy throwing of refuse to the dump, he said, he has marked with a twig the place where he thinks the Swanscombe camp site is to be found. Another two or three seasons should show whether he is right.

PULSARS

Crab Pulsar and its Planet

from our Cosmology Correspondent

With the growing evidence that the entire source of energy for the Crab Nebula lies in the rotating neutron star believed to be associated with the pulsar NP 0532, several attempts have been made to determine the mechanism linking the two physically separated parts of this system, namely the small central star and the large expanding shell of luminous matter. These have been hampered by incomplete understanding of the processes producing supernovae and neutron stars, but A. Cavaliere and F. Pacini have now been able to describe in reasonably accurate terms the evolution of a supernova remnant which does contain a central rotating dense star. The star is taken to be coupled to the remnant largely through the electromagnetic forces involved, because gravitational radiation and mass loss subsequent to the original explosion seem likely to produce only small effects. Cavaliere and Pacini find (*Astrophys. J. Lett.*, **159**, 21; 1970) that the rate of decrease in luminosity of a remnant at any time is closely linked to the observable properties of the central neutron star, and that these parameters when measured for NP 0532 are in good agreement with the theory. The only other known supernova remnant with a radio emission which decreases measurably is Cas A, for which the model predicts an associated pulsar with period $\lesssim 0{\cdot}7$ s. Unfortunately, it seems unlikely that pulsed radiation from this source will be detected if the most widely favoured models for pulsars are at all correct, for the radiation would be highly directional and unlikely to be orientated towards the Earth.

The recent observations of NP 0532 indicating a quasi-sinusoidal variation in period suggestive of the perturbations due to a planet (D. W. Richards *et al.*, *IAU Circ. No. 2178*) and a sudden variation tentatively explained in terms of a "starquake" (D. W. Richards *et al.*, *IAU Circ. No. 2181*) can now both be explained in terms of disturbances due to a planetary companion. If a pulsar is created abruptly in a sudden explosion involving mass loss, then any associated planet initially in a circular orbit will be forced into an eccentric orbit with eccentricity $e = f\,(1 - f)$, where f is the ejected mass fraction (F. C. Michel, *Astrophys. J. Lett.*, **159**, 25; 1970). As Michel points out, an initially eccentric orbit could thus be changed to a roughly circular orbit, and although this is unlikely it seems the only way to account for the form of the sinusoidal variation in period of NP 0532, assuming that this is indeed caused by a planet.

The more likely case of a roughly circular orbit being changed to one of extreme eccentricity could well result in sudden changes in the pulsar's period as a result of close approaches to the parent body, as seen in both NP 0532 and PSR 0833. The rather short interval between the discovery of these pulsars and their observed sudden changes in period suggests that they each have a companion orbiting roughly once a year, clearly a very reasonable orbital period for planets. Such effects will be repeated regularly so there is a ready test of Michel's model, and if these variations do recur as predicted they should provide a useful tool for determining detailed structure of these pulsars.

SPECTROSCOPY

Broadening of Lines

from a Correspondent

A branch of atomic physics that is advancing rapidly in response to the demands of astronomy and plasma physics is the study of the broadening of spectral lines in gases and plasmas. This was the subject of a meeting held by the Institute of Physics and the Physical Society at Imperial College, London, on February 6, 1970.

Dr H. G. Kuhn (University of Oxford) summarized the two extreme case approximations for line broadening that dominated the theory until recently and are still very useful. These are quasi-static or statistical broadening (valid in the outer wings of a line) in which the motions of the perturbing atoms or ions are neglected, and impact broadening (applicable nearer to the line centre) in which superposition of phase shifts of the emitted radiation due to isolated encounters leads to a Lorentz profile accompanied by a small shift. Kuhn said that some lack of cohesion between theorists and experimenters, due to difficulties encountered by both, is now being overcome and understanding of interatomic forces is increasing.

Professor W. R. Hindmarsh (University of Newcastle upon Tyne) described recent studies with neutral perturbers. The classical Lindholm treatment, assuming pure van der Waals attraction, predicts incorrect line shifts, but agreement is much better when the repulsive interaction at small interatomic distances is included. Dr H. van Regemorter (Observatoire de Meudon) showed that repulsive forces probably account for the bulk of the line width as well. A further effect of complications in the interatomic potential curve is the appearance of satellites on either side of the unperturbed line, some striking examples of which were shown by Dr R. Granier (CNRS, Bellevue, Paris). When broadening is due to identical—as opposed to foreign—atoms, a stronger (dipole) interaction occurs. Dr D. N. Stacey (University of Oxford) showed that the theory of this resonance broadening effect is successful except at very low pressures where natural damping may invalidate the impact approximation. Dr C. Baron (Rank Precision Industries, Leeds) described experiments on pressure broadening of Zeeman components in a magnetic field.

The theory of broadening by charged perturbers has been greatly improved recently by the work of Baranger, Griem and others, but some problems remain.

Dr D. D. Burgess (Imperial College, London) explored a new approach based on the laws of conservation of energy and momentum which helps to define the basic assumptions and limitations of other theories. Dr Gillian Peach (University College, London) presented accurate quantum mechanical calculations of electron-scattering cross-sections required for impact broadening theory; her results agreed with semi-classical calculations, but less well with experiment.

The theory of spectral line broadening is very important in astrophysics. Dr B. E. J. Pagel (Royal Greenwich Observatory) described its application to visible effects in stellar spectra (for example, the forbidden satellite lines of helium) to the determination of stellar temperatures and gravities from hydrogen-line profiles and to abundance determinations in stellar atmospheres. The vexatious problem of solar iron abundance, in particular, was closely tied to uncertainties in collision broadening. The helium satellites also formed the subject of a laboratory investigation described by Mr C. J. Cairns (Imperial College, London) which gave results agreeing well with the theory (although theorists are not agreed about its validity). In a similar vein, Dr A. N. Prasad (University of Liverpool) showed how both temperature and density of a hot plasma could be deduced from the profile of He II λ4686.

ATOMIC BEAMS

Relativity in Action

A NEW method devised to measure the velocity of a beam of atoms exploits the relativistic relationship between an electric and a magnetic field and seems to be significantly more accurate than the usual method based on the time of flight. T. S. Stein *et al.* (*Appl. Phys. Lett.*, **16**, 1; 1970) have passed a beam of sodium atoms through a region containing electric and magnetic fields, and by comparing the magnetic effect of the electric field with a known magnetic field they have obtained an accurate measure of the mean velocity of the beam.

It is rare to find a relativistic effect that is of value at velocities as low as 10^4 cm/s, or one millionth the velocity of light. The basis of the method is to apply a constant magnetic field to separate the energy levels of the atoms, followed by a radio frequency field divided into two separate coils. Transitions of the normal Zeeman type are induced and an interference pattern appears in the counter. The magnetic effect of the constant electric field is then to shift the position of the interference pattern, and by adjusting the counter to monitor the position of largest slope on the pattern very small shifts can be detected.

Stein *et al.* point out that this method can be refined to a high degree of precision. Increased accuracy is obtained by continuously reversing the electric field, and by varying the magnetic field a plot can be obtained which gives the mean velocity of the beam as its slope. A weakness of the system, however, is that the mean velocity only is measured, whereas with time of flight techniques the whole velocity distribution is obtained.

The relativistic method was devised as a byproduct of an experiment to measure the electric dipole moment of alkali atoms, and Stein *et al.* have used it on both sodium and caesium atoms. What other particles may be tracked by this method? One suggestion is that a new attempt might be made to see if the neutron possesses a small electric dipole moment. Although no such moment would be expected, the uncertainty in nuclear conservation laws suggests that such a search may indeed be profitable.

GEOPHYSICS

Earth and Oceans

from a Correspondent

THE boom in Australian minerals provided the central theme for the international conference on geophysics of the Earth and oceans, held in Sydney from January 19 to 23, when the emphasis was on exploration. Dr F. S. Grant (Kenting Exploration), outlining the role of mineral exploration over the next ten years, stressed that, as in petroleum geophysics research in the past ten years, developments in mining geophysics would be due to refinements in data processing and techniques of interpretation, rather than any marked advances in instrumentation or field techniques.

Mr M. Talwani (Lamont–Doherty Geological Survey), who explained the principles of satellite navigation and the future world wide VLF–Omega system, presented case histories which were a favourable comment on the use of such methods in deep water geophysical surveys. The value of remote sensing techniques was brought out particularly by Mr R. Bennett (Geophoto Services), who showed how knowledge of the relative concentrations of isotopes in different formations can be used as an aid to delineating lithology by airborne gamma ray spectrometry.

Induced polarization is a very important exploration tool in Australia. Case histories reviewed by Dr S. H. Ward (University of California, Berkeley) indicated that best resolution could be obtained using the dipole–dipole array, and that the percentage frequency effect was to be preferred to the metal factor as a useful diagnostic parameter. Mr G. Omnes (Compagnie Générale de Géophysique) pointed out that induced polarization is the only satisfactory electrical conduction method to delineate massive and disseminated sulphides in areas of West Australia where there are low resistivity overburdens.

When attention turned to magnetism, Dr N. C. Steenland (GAI–GMX, Texas) showed how successful aeromagnetic surveys have been in the search for petroleum fields. He has found that an interpretation based on raw magnetic data is often more significant than results obtained from complex data analysis. Mr G. A. Young (Bureau of Mineral Resources) derived a geological map from airborne magnetic data, and on it the disposition of greenstone belts was clearly indicated, highlighting the interesting areas where the search for base metals should be concentrated.

Naturally, no geophysical conference would be complete without a discussion of continental drift. A special session on rock and palaeomagnetism was introduced by Professor S. K. Runcorn (University of Newcastle upon Tyne) with a general lecture on continental drift, mantle convection currents and tectonics. Mr G. Luck and Mr M. W. McElhinny (Australian National University) presented the first definitive palaeomagnetic results for Australia and India for the Lower Palaeozoic era. Their reconstruction of Gondwanaland was in general agreement with previous theories.

COMPOSITE MATERIALS

Strong Fibrous Solids

from our Materials Science Correspondent

THE growing interest and importance of strong fibrous solids were underlined by the Royal Society's discussion on this topic held in London on January 29. Mr W. Watt (Royal Aircraft Establishment, Farnborough) summarized the structural changes believed to take place in polyacrylonitrile (PAN) fibres during progressive heating in oxidizing or neutral atmospheres, with or without tensile stress, and the associated changes in properties at each stage. He emphasized that the statistical variability in tensile strength depended substantially on sample length, which indicates the importance of defects in limiting the strength. It is uncertain whether the vital defects are the inclusions, or the elongated pores recently established by diffuse X-ray scattering and electron microscopy. Watt stressed the paucity of knowledge about structural changes in PAN, for example, concerning the degree of crystallinity induced by drawing, and called for intensive investigation. The opinion was often expressed at the meeting that the technology of fibre composites has too far outstripped scientific understanding.

Dr R. J. E. Glenny (National Gas Turbine Establishment, Farnborough) recounted systematic experiments on the use of fibre composites based on refractory matrices specifically for use in gas turbine blades. On the basis of the criteria of density, strength and chemical compatibility, attention was focused on a nickel-base matrix with wires of tungsten or tungsten/rhenium alloy, Mo-RTZ alloy or alumina. Vacuum-casting of blade shapes in a cored shell-mould gave excellently uniform filament distribution and it proved possible to incorporate clear channels for coolant. Tungsten and alumina were the most promising reinforcements. Strength levels were marginally less than predicted by the rule of mixtures, and fatigue behaviour was little affected by the presence of filaments. It is too soon to be sure of the future scope of these techniques, but in view of the fact that niobium and chromium alloys are not considered to be equal to expectations filament-reinforcement seems to be the most promising way to improve on the intrinsic properties of nickel superalloys.

Dr J. Nixdorf (Battelle-Institut, Frankfurt) described the pilot-plant production of various strong metallic microwires, including wire of a marageing steel. The technique involves melting a metal rod held in a viscous glass mantle (which acts as both container and lubricant) and rapidly drawing the assembly through a die. Afterwards the glass covering is removed. The strength is attributed not only to the small diameter of a few microns but also to the rapid cooling. A particularly small statistical variability of the wire strength was claimed, and the mean strength exceeded that of boron but was less than that of E-glass. Little was said about stiffness. Various composites have been made with both metallic and polymeric matrices, and for concentrated composites a UTS better than for boron or carbon reinforcement was claimed. The production cost of microwires (on a scale resembling the present scale of production of carbon fibres) was assessed at some tens of pounds sterling per kg. Oddly enough, the audience made no reaction to these intriguing disclosures.

Describing the development of 'Hyfil' (carbon fibre-reinforced) compressor blades in Rolls-Royce jet engines, Mr J. I. Goatham (Rolls-Royce, Derby) emphasized the extensive testing procedures needed, both for development and for routine testing, including such exotic methods as holography. He also mentioned the great importance of joints and attachments, where critical losses of weight advantage can easily be sustained by faulty design. He was the only speaker to emphasize the joining problem, though the chairman, Dr A. H. Cottrell (Cabinet Office, London), expressed the view that this central problem was well on the way to being vanquished.

Dr F. J. McGarry (Massachusetts Institute of Technology) reported work on epoxy resin toughened by elastomer dispersions—following the example of rubber-reinforced polystyrene described at the Royal Society in 1963. The impressive increase in fracture toughness which was achieved seemed to depend in part on achieving an optimal degree of cross-linking of the elastomer, as well as a bimodal distribution of coarse and fine elastomer particles. McGarry postulated that coarse particles favour crazing of the matrix, which absorbs energy, while small particles promote shearing of the polymer matrix, which again absorbs energy. The ultimate aim is to use the toughened polymer as a matrix for fibre-reinforced building materials. The potential of the building industry as a consumer of composites was stressed by Dr A. J. Majumdar (Building Research Station, Watford), who showed how concrete or plaster panels could be toughened by incorporating (through a co-spraying technique) fibres of special zirconia-bearing glass which can stand up to the corrosive alkaline environment in concrete (there is no special problem with plaster). Majumdar explained that plaster panels thus reinforced will stand up to the repeated impact from primary school children.

Dr A. Kelly (National Physical Laboratory, Teddington) continued the theoretical approach by analysing the dependence of work of fracture on the length and diameter of fibres. It transpired, to the surprise of many, that from this point of view thick fibres were preferable. In brittle/ductile composites, thick fibres favour plastic deformation over large volumes of a ductile matrix, while in brittle/brittle composites, thick fibres suffer pull-out over greater lengths, with the increased associated frictional energy loss. Thus two physically quite distinct processes between them lead to a law of general validity for fibre composites.

Professor F. C. Frank (University of Bristol) assessed the ideal stiffness of a carbon chain by various means (infrared spectroscopy, calculations from the characteristics of diamond and so on) and was led to a value of 2–2·5 Mbar. The best value obtained in practice is apparently about ten times less than this, though it might have been predicted that hard-drawing, of nylon, for example, should reduce this factor of disparity. Frank went on to describe some special structures which seemed to consist of a stiff polymeric spine with built-in polymeric beads, which might open the way to a polymer–fibre-reinforced polymeric matrix. He predicted that quite soon the polymer industry, in search of higher strength, would turn to more elaborate production methods, even though this would diminish one of the chief advantages of polymers, their cheap fabrication.

Will your mind stop growing?

Will your mind stop growing when you've left university? Or will you remain flexible enough to join a company which is at the centre of change: inventing, developing and improving its products and processes all the time?

Flexibility, talent and a taste for responsibility is what ICI looks for. And if you've got it, you can go to the top with it.

Each year ICI selects about 500 graduates from British universities. That's how many are needed to maintain the present rate of diversification.

Our research, design, development and production departments demand graduates from nearly all scientific and technological disciplines: while graduates in any subject, including arts and social sciences, are considered for sales, marketing, management services, personnel, purchasing and distribution.

But that is just where it starts. Your degree subject will not limit you: peoples' talents develop in many different types of job and in many different places.

That's why, for example, you may find engineers, historians, chemists, physicists and specialists in other disciplines, all working together – building a factory in Holland, selling paint in Peterborough, giving technical advice to customers in Istanbul.

Why not talk to us?

Each spring term ICI representatives visit your university. Ask your Appointments Officer to fix up a meeting for you and learn about the opportunities which ICI can offer you.

Central Personnel Department,
Imperial Chemical Industries Ltd.,
Millbank, London, SW1.

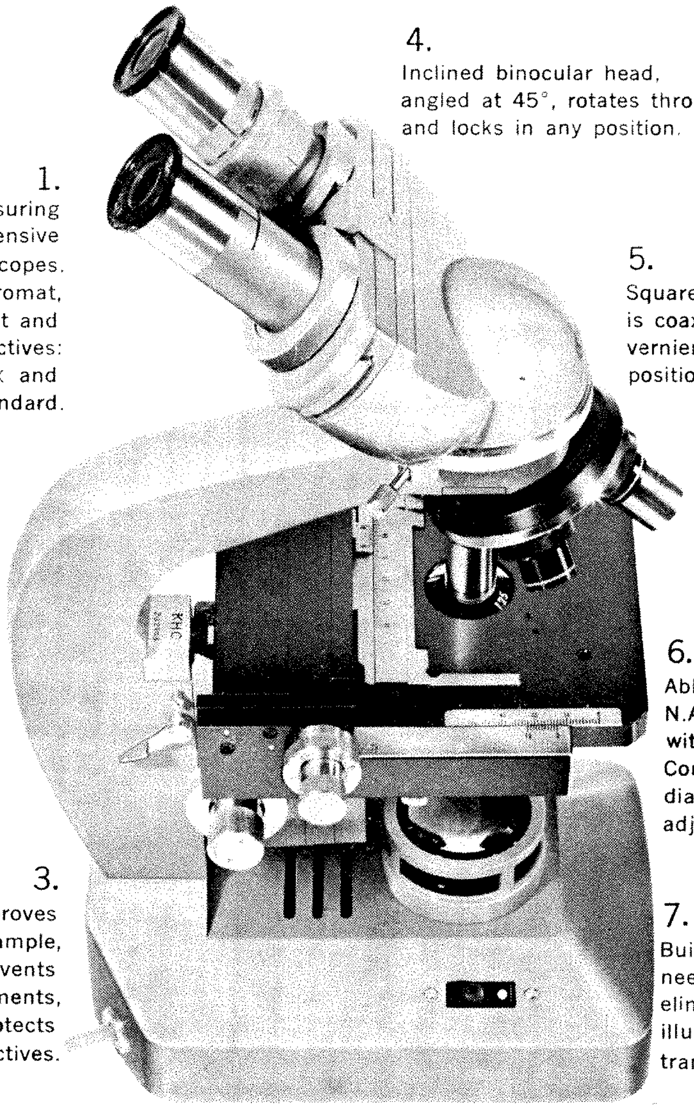
Olympus KHC is top choice for latest features and low budget



4.
Inclined binocular head, angled at 45°, rotates through 360° and locks in any position.

1.
Wide field or measuring eyepieces as in expensive research microscopes. Highest quality Achromat, Plan Achromat and Fluorite objectives: Achromat 4×, 10×, 40× and 100× (oil) standard.

5.
Square mechanical stage is coaxially-controlled and vernier calibrated to give exact positioning of slides.

2.
Fine and coarse focusing knobs are coaxial and positioned low for ease of operation.

6.
Abbe type condenser, N.A: 125, is focusable with rack and pinion. Continuously variable iris diaphragm allows adjustment of illumination.

3.
Modern design improves handling ease. For example, vertical stage focusing prevents distracting head movements, and pre-set focus lock protects slides and objectives.

7.
Built-in 20-watt illuminator needs no centering, eliminates accessory illuminators and transformers.

Olympus KHC is the latest improvement for everyday laboratory work, a microscope for the lowest budget and still featuring eye-fatigue-free clearness and high precision. Its seven outstanding features have made KHC the most used and valued instrument for medical students and laboratory workers all over the world.
Total magnification: 40x~1000x

Problems of Expanding Populations

by
D. WOLFERS
Population Bureau,
Eland House,
London SW1

The most serious demographic problem at present is in the developing nations, where populations are growing at a rate of between twenty and forty per thousand per year. Many programmes of birth control are hampered by factors such as child mortality and cultural traditions, but this survey of the world situation shows that these problems are not insuperable if tackled realistically.

THE current human ecological crisis derives from the great technical advances by which man has placed himself in the position of a (self)-protected species for whom natural ecological regulation is suspended. Inevitably his numbers have increased to the point where all the resources of the Earth cannot supply his wants.

There have been four distinct forms of organization of human life—arboreal, pastoral, agricultural and technological—and each change from a more primitive to a more advanced organization has been accompanied by the disturbance of an established population balance, followed by a phase of rapid growth, and then the re-establishment of demographic stability. We are at present involved in the latest of these transformations and, with the limited perspective of the human life-span, have difficulty in seeing how it will end.

In each of the three past states of demographic balance, corresponding to arboreal, pastoral and agricultural society, that balance was determined by natural principles so that, growth being inhibited by the unchanging abundance of resources, death rates automatically adjusted to the prevailing birth rate. This adjustment did not mean that birth and death rates were the same every year, but there were periodic peaks of deaths, brought about by famine, epidemic or war, which irregularly restored a supportable population density (Fig. 1). The current imbalance is likely to be resolved on similar terms if direct action is not taken to avoid it. But we now have the technical and social means of restoring a balance on terms more acceptable to human aspirations than the natural balancing mechanism.

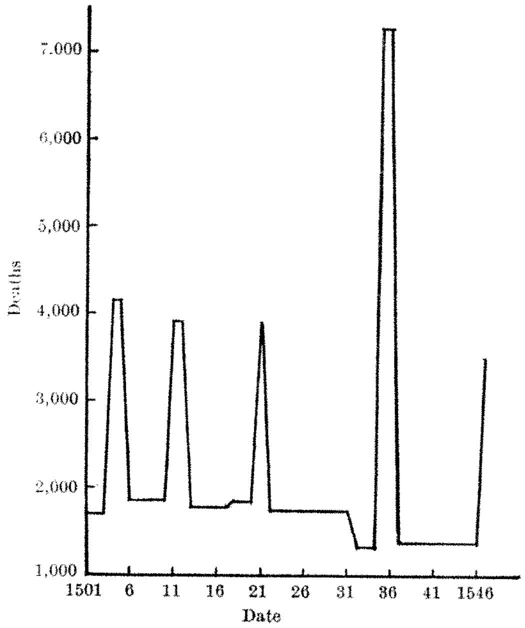

Fig. 1. Annual deaths in Augsberg from 1501 to 1547. From ref. 1.

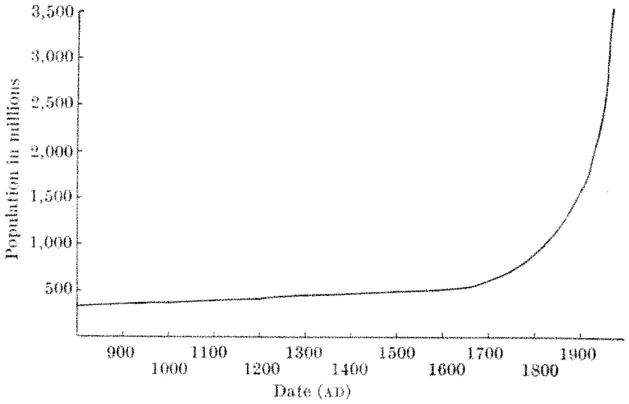

Fig. 2. The growth of the world population from AD 800 to 1969.

Population trends in the 10,000 years of the agricultural phase (Fig. 2) show that throughout this period minor improvements in the availability of resources made possible slow but distinct growth of world population at a rate somewhat less than one per thousand per year. Meanwhile, high birth and death rates (about forty per thousand) prevailed constantly, and populations were everywhere and at all times "young" (Fig. 3).

Early Disturbances of Balance

The first stirrings of disturbance of this balance are now seen to have begun in about 1650 when, in response to quite small improvements in agricultural practice, and perhaps also political organization, the rate of growth of world population more than trebled to about three per thousand per year. This change occurred simultaneously in Europe and Asia. In 1750, with the agricultural revolution in full swing and the effects of the industrial revolution beginning to be felt, it is clear that a major discontinuity had occurred in those countries that were affected; growth rates started increasing to levels like ten to fifteen per thousand per year. By now, production was leaping ahead of consumption and the determining factors of rates of

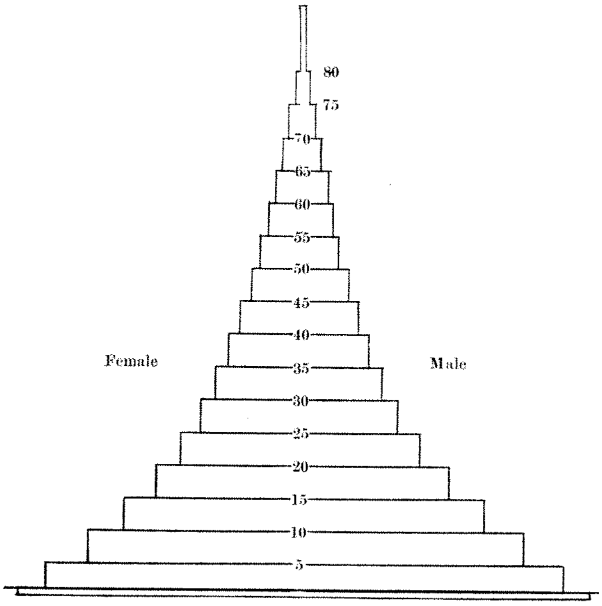

Fig. 3. The age–sex distribution of the population of Mexico in 1966. The total population was 44,145,000.

growth ceased for the time being to be economic and became biological; the link between birth and death rates was broken and they were able to act as independent variables.

The first effect of this change was the disappearance of mortality peaks. Food production and distribution had so improved that adverse seasons no longer produced famine, and nutritional standards had so changed that even though conditions of crowding and sanitation may have been worse than ever, epidemic disease was no longer able to decimate populations. Political organization had become so macroscopic that the toll of warfare became too selective to have important demographic consequences. Next came a steady decline of annual death rates in response to innovations in environmental sanitation and curative medicine and rising standards of nutrition—a process still continuing although with diminishing returns. The third effect, delayed for more than a century after the initiation of the first, was the long steady decline in birth rate, stretching in the United Kingdom over the whole period 1880–1930. No contemporary analysis of the causes of this decline exists, but it is safe to say that it reflected the adjustments made by individuals to radical changes in conditions of economic and social competition. An important secondary effect of this decline in birth rates was the transformation of the population to an older age-distribution (Fig. 4), with a consequent braking effect on the decline in death rate and a temporary alleviation of the dependency burden.

From 1930 onwards little change has been registered in the demographic indices of developed countries, growth rates fluctuating between three and ten per thousand per year, with manifest full independence of death rates from birth rates.

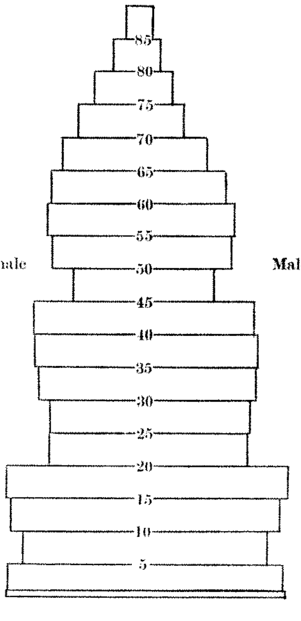

Fig. 4. The age–sex distribution of the population of France in 1965. The total population was 48,918,697.

The Developing World

Although such high growth rates cannot continue for ever, they can be sustained for some generations without bringing inevitable disaster. The current crisis arises from a recognition of the potential consequences of continuation of the quite different trends in the developing world.

By the beginning of the twentieth century, moderate growth rates of about ten per thousand prevailed in most agricultural lands. This situation reflected the pacification, aggregation and administration imposed by the colonial powers and tutelary agents. Public health advances, particularly in tropical medicine, began to reduce the force of epidemic scourges, and the concept of famine relief made some progress. It is, however, only since the Second World War that a manifestly insupportable imbalance has been recognized. Countries which in 1939 were economically and socially stagnating in subsistence agriculture emerged in 1945 with political groups determined to speed them into the maelstrom of the modern world. Not only was production set for continuous expansion and mechanization, but a new spirit of interdependence led to the limited redistribution of foodstuffs under the aegis of United Nations agencies and with the help of food surpluses in advanced countries. Although violence was involved in the achievement of political independence by many developing nations, the previous pattern of recurrent tribal raiding was prohibited by the consolidation of what were in pre-colonial days dozens or hundreds of autonomous groups into large nation states. With neither famine nor war to restrain numbers, the importance of the spectacular application of preventive medical techniques (often, as with DDT and penicillin, developed during the Second World War) was enhanced, and death rates declined throughout the world at an unprecedented rate.

Rate of Growth Today

Fig. 5 illustrates the mondiality of this trend, and its size. Growth rates in developing countries at present vary between twenty and forty per thousand per year, representing, on exponential projection, periods of doubling of between 18 and 35 years. The most generally accepted estimate of the current growth of world population is twenty-one per thousand (doubling every 33 years) with a strong accelerating trend (Fig. 2). Estimates of the probable future of development of world population

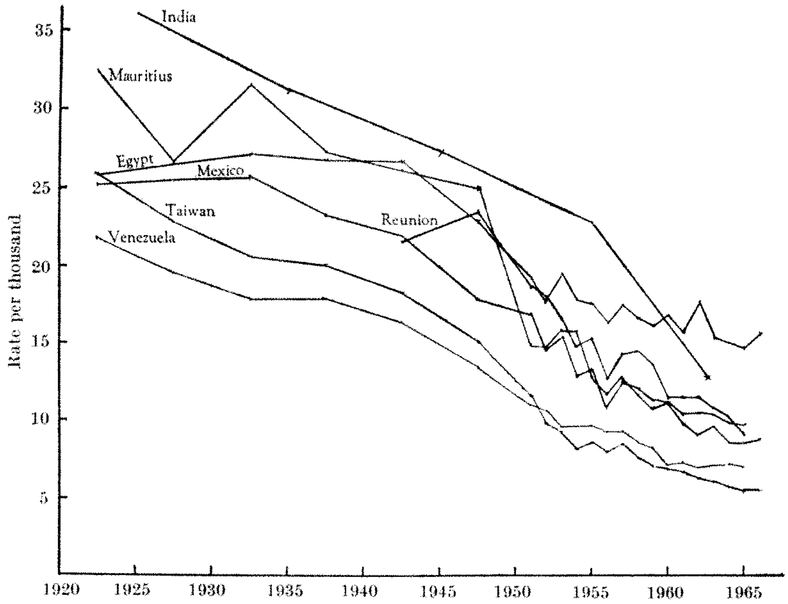

Fig. 5. Crude death rates of selected countries, 1920 to 1966. From ref. 2.

prepared by the UN Demographic Division suggest a total of 7,000 million by the year 2000 compared with the present 3,500 million.

The expansion of a species ten-fold in a mere fourteen generations is, of course, a remarkable success story—in view of the complexity of human requirements it is almost a miracle of adaptation. Furthermore, there can be no doubt that when the limits of sustenance are reached the increase will be arrested by the customary balancing mechanisms of ecological logic.

Although some people believe that the problem can therefore be safely left to solve itself, the likely resolution without deliberate action is not the introduction of low birth rates but the restoration of high death rates. The spontaneous orderly unfolding of a demographic-economic transition is most improbable in the circumstances of the developing world, for the cause and effect sequences which led to the slowing of European growth are all running in reverse. Population growth, death control and the expansion of the labour force are proceeding rapidly while those whose job it is to increase economic growth, birth control and employment opportunities strive to keep pace. The problems of capital formation are particularly acute, for not only are the demands for capital inputs to support the expanding population crippling, but the ruthless reservation of resources for capital at the expense of consumption, which darkened the lives of town dwellers in nineteenth century Europe and starved the peasants of Russia in the 1930s, is no longer morally acceptable. By increasing the denominator of every fraction, be it literacy rate, doctor-patient ratio, proportion of labour force gainfully employed, or income per head, a rapid rate of population growth leaves government and people producing frantically in order to maintain their situation. Although economies of scale may accrue as the population increases in some countries, in most the scale is already so great that no real effect of this kind can be demonstrated. While in some countries with vast hinterlands no perceptible change is taking place in the ratio of population to natural resources, in others this ratio is becoming critically high, and in yet others, principally small islands, actual space is running out. Because the flow of international migration is blocked in almost every channel and will surely remain so, these islands are experiencing the crisis in its most acute form. Because of these considerations, if no action is taken to limit population growth it is likely to continue with no substantial change in standard of living or national economy until the problem becomes too great to cope with and the system itself collapses under the administrative burden of numbers and the disappointment of perpetual deferment of hopes. If this should happen, large tracts of the Earth will return to jungle law, de-population will take place and an entirely new set of problems will arise.

This catastrophe is not an immediate prospect, nor likely to occur on a world-wide scale. Some favoured developing countries, such as Singapore, Venezuela and Israel, have rates of economic growth large enough to sustain the chain reaction of development long enough to produce the social changes which we assume to be sufficient to stimulate spontaneous fertility limitation; others are sufficiently sparsely populated in relation to their resources to be able to grow rapidly for a very long time before there is a qualitative change from rural poverty to chaotic destitution. But these countries will, if they do not act soon to limit growth rates, have missed the only foreseeable opportunity to build graciously advanced societies free of the tragic squalor which has accompanied industrialization and demographic transition in the western world.

World Situation

While each country faces its own population dilemma, the world as a whole is not exempt. The "green revolution" has given a temporary advantage in the race to keep world food supplies from becoming yet more inadequate to meet growing needs; modern public health makes it difficult to visualize uncontrollable pandemics sweeping the world; nuclear weapons appear at present to be held under firm restraint. The crucial areas of world concern are now atmospheric pollution, shortage of water and the potential exhaustion of minable minerals. In these respects we live in a fool's paradise where each has faith in the ability of the others to solve problems too difficult for himself. Aesthetically too, and in relation to the intangible "quality of life", more and more people, unable to visualize institutions which can preserve what man has held valuable in the past into a teeming future, view that future with perhaps unwarranted despair.

Action is, however, being taken. In almost all cases this takes the form of family planning programmes, fully organized by government, supported by government or permitted by government. The pattern of introduction of these programmes was, only 10 years ago, a rather unedifying spectacle in which enthusiastic voluntary agencies seemed to drag suspicious governments into a series of tentative steps. Only after feeling their way for some years did governments come to embrace programmes enthusiastically. This situation is now changing, and genuine government leadership is appearing in an encouragingly large number of countries.

Government reluctance, and in places opposition, stems from several considerations, of which the fear of provoking opposition and courting unpopularity is the least realistic and the most important. It is in dispelling the myth that most peasant populations would be outraged by exposure to birth control services and propaganda that the social survey has made its outstanding contribution to the solution of the problem. Sample surveys, referred to as KAP surveys (knowledge, attitude and practice), conducted in dozens of different settings, seem to have uncovered a very strong demand—commonly 70 to 80 per cent of female respondents—for the facilities for controlling fertility, and to have demonstrated that, almost regardless of the situation prevailing, most couples want relatively small families (three or four children). There have been some exceptions to these generalizations, particularly in tropical Africa.

Difficulty also arises in countries where political power is shared between two or more ethnic or tribal groups of approximately equal numbers. In these circumstances each group fears that their own members, by adopting family planning, will encompass their ultimate political extinction. The view is quite widely and influentially held in Africa and Latin America that "population control for the developing countries" is a manifestation of similar tribal thinking on a global scale by the developed countries, and this naturally is responsible for bitter opposition.

The unreal basis of official Roman Catholic thought on the subject hinders developments in predominantly Catholic countries, but family planning programmes with declared health and welfare objectives substituted for demographic aims are making headway.

Outcome of Programmes

It is too early to make more than the most tentative predictions of success or failure for family planning programmes, and it is likely that some will be successful and others fail. The population control objective requires that two stages be accomplished. First, the adoption of birth control by most of the population efficiently enough to ensure that births correspond closely with numbers desired, and, second, the reduction of numbers desired to the level where development success is assured.

The first is certainly an easier objective to attain than the second, but, except in a few cases, which as they appear come to be described as special, there is little encouraging to report yet. For reasons related to the austerity of Christian morality, contraceptive technology has received far too little attention from scientists in the past. The crisis has arrived when we have no satisfactory techniques of contraception to offer the clients recruited in these programmes. Methods which have proved successful for highly motivated western populations are either too difficult or unpleasant for the mildly motivated to use regularly (diaphragm, condom); have too many unwelcome side-effects (IUD, pill, injection); require an unrealistic degree of cooperation (pill) or are too ineffective (coitus interruptus, spermicidal preparations). Although many millions in the developing world are struggling to use these methods, follow-up studies show that no more than half are able to persevere with any one method for a prolonged period. The techniques of sterilization, particularly of males, are much more satisfactory, but their adoption requires a finality of decision which few can muster until their family sizes are already excessive. The uncertainty of survival in areas where rates of infant mortality are high is, of course, a further deterrent.

The demographic history of Japan in the 1950s and contemporary East Europe shows that the practice of abortion alone is capable of producing dramatic effects on the birth rate, but the applicability of this to less developed countries is dubious. Neither the level of motivation nor the availability of medical services is of the same order in most of these. Additionally, stubborn adherence to rigid interpretations of the sanctity of life, particularly in Moslem and Catholic countries, rules out this method at present.

It is not known whether the availability of more acceptable forms of contraception (and much current research is being devoted to their development) would have a favourable effect on the numbers of couples adopting contraception, but it is certain that it would enhance the effectiveness of practice of those who do.

The discrepancy between the proportions of any population studied who assert their willingness to practise contraception and those who actually do so when it is offered is very large, and offers a great challenge to the social scientist and psychologist to unravel the complexities of decision taking involved. One of the least understood factors is the part played by males in this process.

Family planning programmes with demographic objectives are recent innovations. The earliest was in 1952 (India) but remained in very low gear till 1964. The real history of such programmes dates back only to 1962. So far very few participating countries have recorded substantial gains, and there is no lack of critics who attribute these to factors other than deliberate programmes. Although no change has been recorded in the birth rates of countries such as India and Pakistan, it should be remembered that in these countries vital registration is grossly defective, that changes in the age structure of the population are producing conditions favourable to increasing birth rates and that millions of couples have attempted birth control for the first time during the past few years.

High Fertility Favoured

The complementary task of introducing the "small family norm" has, in spite of considerable effort, met even less demonstrable success. While families of three children or fewer "fit" urban, industrialized societies which put premiums on higher education and provide comprehensive welfare services, it is the large family which until recently has enjoyed advantages in the rural environment which still prevails for 80 per cent of people living in developing countries. Free labour for the farm and the security of numbers and continuity in ill health or old age were the principal economic gains, while the extended family system spread the very light burdens of child-rearing in such a way that each additional child was almost no extra burden. Because very high levels of child mortality prevailed until recently, it is not surprising that a mutually supporting structure of social, moral and religious doctrine has developed to protect and advance the ideal of high fertility. It matters little that, after a generation of rapid increase, fragmentation of farms has become more important than labour supply, and after a generation of independence the burden of education is growing to rival the benefits of mutual support; the time scale of change in social and economic institutions is now far more contracted than that of change in cultural outlook. Automatic re-acculturization cannot be relied on, and the task of changing attitudes falls to the propagandist, the educator, and perhaps soon the tax gatherer.

The "small family norm" will not, of course, make any headway where extreme levels of child mortality prevail, so that a precondition of lowering birth rates is the necessity to lower death rates. The most urgent preparatory task is to improve the coverage and standards of maternal and child health services in rural areas of the developing world; this is, of course, enormously costly. It is only, however, in the context of a secure and comprehensive health service that family planning can cease to be a foreign gimmick and become a settled part of life.

Campaign Media

Posters, films, radio talks and earnest face to face encounters multiply throughout the developing world to bring the message that two or three children are enough, but, in the hectic urgency of this campaign, time has not been found to evaluate the efficacy of the media used. The possibility of attempting to indoctrinate school children is at last being canvassed, but there is resistance because of the sexual component involved. School activity, to be effective, must take place in primary schools, because too few children attend higher grades for a campaign to have worthwhile results. Numerous suggestions for giving financial incentives to parents to have small families or imposing penalties on those who have large ones have been made. Almost without exception* these prove relatively easy to implement in the highly organized money economy of an industrial state, which does not need them, but quite impossible in areas of subsistence agriculture where taxpayers form a small élite of the population. Meanwhile, the world is not ready to surrender another of its primitive freedoms by accepting the introduction of licences for childbirth.

If no way has been found to manipulate family size norms, the same may be said for the determination of optimum levels to aim for. Although in a technologically stagnant world, with abundant space and goods, a case might be made for aiming at a zero rate of growth, this magic figure has no applicability to any actual situation in the world today.

Although many programmes express their objectives in terms of the attainment of specific rates of growth by a certain date, few if any of these objectives have a more rational basis than the hope that the objective can be attained. So many ecological studies have been made too late that there is clearly a great urgency for the revival of studies of optimal population growth so that, when conditions are achieved which permit the induction of massive changes in fertility, a rational policy will be possible.

The situation at present is undeniably confused, with hope and despair about evenly balanced. This is inevitable in the first decade of serious attempts to deal with a problem of this size. Clear outlines of the tasks to be performed are, however, beginning to emerge. Of these, surely the most difficult and most important is to reduce child mortality as far as possible and provide a comprehensive network of health services throughout the developing world. This is the carrier wave for broadcasting family planning. A process of re-acculturization must be accomplished, and this implies indoctrination of populations at impressionable ages—in early school years, and as a corollary it implies bringing the whole child population to school. To these extents, medical and educational, population control depends on progress in development. There are, however, activities which may bring results in relatively unpromising situations. It is agreed that too frequent child-bearing is physically harmful to women, and this may form the basis for the adoption of a more authoritarian attitude to the prescription of contraception by members of the medical profession and their agents. Were the provision of contraceptive techniques as routine a part of the after-care of childbirth as iron for the treatment of anaemia, or insulin for diabetes, great results might be achieved even in areas now hopelessly unprepared for radical social change.

Impact of Abortion

The liberalization of abortion laws will likewise have an impact, although necessarily one which is dependent on the availability of competent services to perform operations. Meanwhile the search for reliable and safe medical abortifacients must be pursued, as must the search for better contraceptives. For all its moral dubiety, abortion enjoys the enormous psychological advantages of the nine late over the timely one stitch.

It is not easy to assess the ultimate impact of the torrent of "educational" material now inundating adult populations in the developing world. There are good reasons to believe that this insistent reiteration may, after a relatively long time, quite suddenly bring about a change in popular attitudes. Familiarity and legitimation are powerful agents for the dissolution of resistance. Patience is therefore important.

If we look more than a generation or two ahead, we are forced to come to terms with the ecological basis of the problem. At present the human race is appalled by the recognition of its dramatic rise to maturity with the accompanying achievement of the potential for self-destruction, for irretrievable pollution of the environment, and for exhaustion of key materials as well as for overcrowding itself. An age of centralized planning is on us as part of the unavoidable logic of development and progress. That planning already involves production and agriculture, education and welfare, research and development, distribution and transportation, the siting and distribution of population and countless other aspects of our lives. It is inevitable that it will soon come to embrace the numbers and then the quality of population, for all else will come to depend on these.

RNA Polymerase σ-Factor and the Selection of Initiation Site

by
M. SUGIURA

Kyoto University, Kyoto

RNA polymerase lacking σ-factor can transcribe the replicative form of phage fd DNA quite well, but loses the ability to select the appropriate initiation sites on the template, and both strands are transcribed. When σ-factor is added, the specificity and asymmetry of transcription are restored. The σ-factor restricts initiation to specific sites on the DNA template.

BURGESS *et al.*[1] separated *Escherichia coli* RNA polymerase into a core enzyme and a σ-factor by chromatography on phosphocellulose. The factor appears to be identical with the "γ-protein" described by Krakow *et al.*[2]. RNA synthesis on certain templates such as the DNA of bacteriophage T4 was greatly stimulated by addition of σ-factor to the core enzyme. This discovery led to a number of studies suggesting that the σ-factor acts at the level of initiation of RNA synthesis[3–7]. Burgess *et al.*[1] have shown, however, that the core enzyme alone can transcribe calf thymus DNA quite well. This is also the case with the circular double stranded replicative form DNA (RF-I DNA) of phage fd, which was the subject of this study. The species of RNA transcribed on RF-I DNA *in vitro* by the undissociated enzyme have been well characterized[8,9]. Accordingly, we analysed the starting nucleotide sequences as well as the size of the RNA synthesized in the presence and absence of σ-factor. Like the complete enzyme, the core enzyme could initiate RNA synthesis with purine ribonucleoside triphosphates using RF-I DNA as a template. The core enzyme, however, transcribed both strands of the template, and the reaction products were very heterogeneous, in both their starting sequences and their size. If σ-factor was added back, the limitations on transcription were restored and only the minus strand served as a template.

RNA polymerase was prepared from *E. coli* A19 and purified by sucrose density gradient centrifugation[8]. The enzyme was then fractionated into the core enzyme and σ-factor by phosphocellulose column chromatography, according to the method of Burgess *et al.*[1]. RF-I DNA was prepared from *E. coli* K38 cells infected with phage fd as described previously[8]. T4 DNA was prepared from purified phage T4 by the method of Richardson *et al.*[10]. The methods for analysing the starting nucleotide sequences and for measuring the size distribution by band centrifugation have been described[8,9].

Kinetics of RNA Synthesis

The addition of the σ-factor to core enzyme greatly stimulated the RNA-synthesizing activity with T4 DNA and *E. coli* DNA as template (Table 1). By contrast, the core enzyme alone was able to transcribe RF-I DNA with about half the efficiency of the complete enzyme. The difference in template response became more striking at low substrate concentration. A double reciprocal plot of RNA synthesis as a function of the substrate concentration (Fig. 1) was nonlinear, as also noted by Anthony *et al.*[11], who suggested that the concentration of substrates affects both the initiation and polymerization steps. When the concentration of one nucleoside triphosphate was varied and the other three substrates kept at a high concentration (0·4 mM), the double reciprocal plot became nearly linear. The plots for ATP and GTP are shown in Fig. 2. With the complete enzyme, the apparent K_{m} values were low and almost identical for T4 and RF-I DNA templates. By contrast, high apparent K_{m} values were found with the core enzyme, and the values with T4 DNA were conspicuously higher than those with RF-I DNA. The difference in the stimulatory effects of σ-factor on transcription of T4 and RF-I DNA may be a reflexion of these K_{m} values. A detailed study of the kinetics and their implication will be published elsewhere. Vogt[7] suggested that breaks in the DNA template stimulate transcription by the core enzyme. This is not the case with RF-I DNA, for RF-I DNA remained unchanged during transcription[9].

Table 1. STIMULATING ACTIVITY OF σ-FACTOR ON VARIOUS DNA TEMPLATES

DNA	AMP incorporated (nmoles)	
	Core	Core + σ-factor
T4	0·51	5·8
E. coli	0·27	2·8
RF-I DNA of fd	2·7	4·6

The assay mixture (0·5 ml.) contained 40 mM Tris-HCl (*p*H 7·9), 8 mM $MgCl_2$, 40 mM KCl, 0·4 mM each of CTP, UTP, GTP and ^{3}H-ATP (generally labelled, 1,000 c.p.m./nmole), 5 μg DNA and 5 μg core enzyme. About 3 μg of σ-factor was added. Following incubation for 10 min at 37° C, the reaction was terminated by adding 10 per cent trichloroacetic acid–2 mM pyrophosphate, and the ^{3}H-AMP incorporated was assayed by a 'Millipore' filter method.

The 5′-Termini of Products synthesized with and without σ-Factor

Incorporation of the four γ-^{32}P-labelled nucleoside triphosphates into the 5′-termini of RNA was studied. RNA chains formed by the core enzyme were initiated

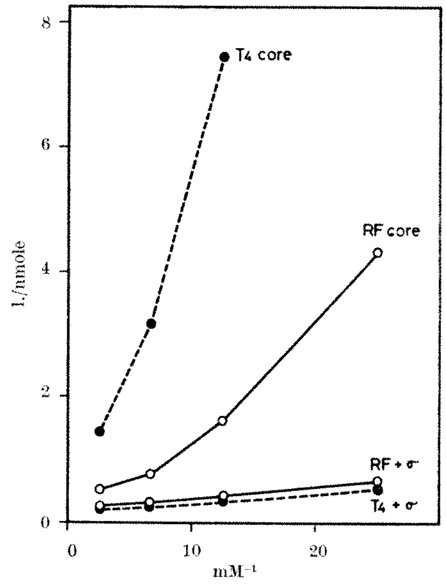

Fig. 1. The effect of varying the concentration of all four nucleoside triphosphates on the rate of RNA synthesis. The assay mixture (0·5 ml.) contained 40 mM Tris-HCl (*p*H 7·9), 8 mM $MgCl_2$, 40 mM KCl, 10 μg DNA, 5 μg core enzyme and increasing concentrations of GTP, CTP, UTP and ^{3}H-ATP from 0·04 mM to 0·4 mM. About 3 μg of σ-factor was added. Following incubation for 10 min at 37° C, the reaction was terminated and the ^{3}H-AMP incorporated was assayed as in the legend to Table 1.

predominantly with purine nucleoside triphosphates (Table 2). The ratio of the terminal ATP to GTP incorporated was similar to that for synthesis by the complete enzyme.

Table 2. INCORPORATION OF NUCLEOSIDE γ-^{32}P-LABELLED TRIPHOSPHATES INTO RNA

Enzyme	Nucleoside γ-^{32}P-triphosphates incorporated (pmoles) CTP	GTP	UTP	ATP	^{3}H-AMP incorporated (nmoles)
Core	0·9	7·2	0·7	4·3	2·4
Core + σ-factor	1·5	14·0	1·3	9·0	5·6

The assay mixture (0·5 ml.) contained 40 mM Tris-HCl (*p*H 7·9), 8 mM $MgCl_2$, 40 mM KCl, 0·2 mM each of nucleoside triphosphates, including a γ-^{32}P-labelled nucleoside triphosphate (about 10^6 c.p.m./nmole) and ^{3}H-ATP, 10 μg RF-I DNA and 5 μg core enzyme. About 3 μg of σ-factor was added. Following incubation for 10 min at 37° C, the mixtures were passed through 'Sephadex *G*-100' columns (1 cm × 20 cm) to remove radioactive substrates. The RNA fractions were pooled, precipitated with cold 10 per cent trichloroacetic acid, and collected on 'Millipore' filters, and the radioactivity was assayed.

We have shown previously[8] that three different species of RNA starting with the sequences pppApUpGp - - - , pppGpUpAp - - - and pppGpUpUp - - - , are synthesized under the direction of RF-I DNA. Accordingly, RNA labelled with either γ-^{32}P-ATP or γ-^{32}P-GTP was prepared in the presence and absence of σ-factor. Following hydrolysis with pancreatic ribonuclease, the resulting radioactive fragments were resolved chromatographically, as described previously[8]. The results are shown in Table 3. With core enzyme, less than 45 per cent of the ^{32}P applied was recovered in the expected areas (pppApPyp and pppGpPyp), and the greatest amount was found in other chromatographic regions. On adding σ-factor the ^{32}P recovered in the expected pppApPyp and pppGpPyp regions was markedly increased and accounted for more than 70 per cent of the total termini. When RNA formed by the core enzyme (labelled with γ-^{32}P-ATP) was hydrolysed with T1 ribonuclease, only 15 per cent of the radioactivity was recovered in the pppApPypGp region. These results indicate that, although the core enzyme could initiate RNA synthesis with purine nucleotides, the chief products differed in their subsequent nucleotide sequences from those formed by the complete enzyme.

Characterization of RNA Products

Hybridization tests were performed according to the procedure previously described[8]. The RNA synthesized by the core enzyme–σ-factor complex could hybridize only with denatured RF DNA, as observed earlier[8]. By contrast, RNA synthesized by isolated core enzyme hybridized with both the single stranded DNA from mature phage and with denatured RF DNA (Table 4). The amount of RNA which hybridized with the denatured RF DNA was about twice that which hybridized with the single stranded DNA (compared on a molar basis). This indicates that, whereas the complete enzyme selectively transcribes only the minus strand of the template, the core enzyme lacks this specificity and transcribes both strands of the template.

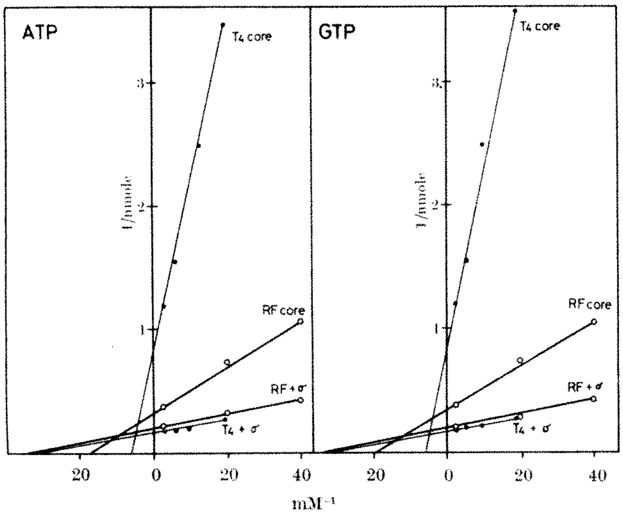

Fig. 2. The effect of varying a single nucleoside triphosphate concentration on the rate of RNA synthesis. The reaction volume, contents and incubation were as described in the legend to Fig. 1, except that one nucleotide, ^{3}H-ATP or ^{3}H-GTP, was varied and the concentrations of the other three nucleotides were fixed at 0·4 mM.

The RNA species starting with pppA - - - has a size of about 26S, and represents nearly one turn of the template[9]. Accordingly, RNA containing γ-^{32}P-ATP was synthesized with and without σ-factor and analysed by band centrifugation. An excess template condition (see ref. 9) was used for the RNA synthesis, because the core enzyme can transcribe both strands of the RF-I DNA template and thus move in either direction on the template. The molar ratio of enzyme to template in the reaction mixtures was estimated to be roughly 1 : 1, assuming that the molecular weights of the core enzyme and RF-I DNA are 4×10^5 and 3×10^6 daltons, respectively.

The sedimentation profiles of the synthesized products are shown in Fig. 3. The undissociated enzyme gave rise to a major peak at about 26S, with a shoulder toward the lighter region (Fig. 3*A*). The shoulder was assumed to correspond to the nascent RNA chains, because the 26S peak became much sharper and the shoulder disappeared when the termini of RNA chains were pulse-labelled as described previously[9]. By sharp contrast with this pattern, the RNA formed by the core enzyme was found distributed throughout the gradient (Fig. 3*B*). Although synthesis of RNA with the core enzyme was performed for an additional 20 min, no increase in ^{32}P at the 26S region was observed. On adding σ-factor to the core

Table 3. RECOVERY OF ^{32}P IN THE FRAGMENTS PRODUCED BY DIGESTION OF RNA LABELLED WITH γ-^{32}P-ATP AND γ-^{32}P-GTP WITH PANCREATIC RIBONUCLEASE

Fragments	(γ-^{32}P-ATP)-RNA Core	Core + σ-factor	Fragments	(γ-^{32}P-GTP)-RNA Core	Core + σ-factor
pppApPyp	44·3	79·1	pppGpPyp	40·3	73·1
pppApPupPyp	13·6	11·6	pppGpPupPyp	13·5	6·8
pppAp(Pup)$_2$Pyp	8·2	4·2	pppGp(Pup)$_2$Pyp	8·4	8·0
pppAp(Pup)$_3$Pyp	12·4	1·6	pppGp(Pup)$_3$Pyp	6·8	4·2
≥pppAp(Pup)$_4$Pyp	21·5	3·5	≥pppGp(Pup)$_4$Pyp	30·9	7·9

RNA labelled with γ-^{32}P-ATP and γ-^{32}P-GTP was synthesized by RNA polymerase with and without σ-factor, as in the legend to Table 2. The products were extracted by treatment with 80 per cent phenol and then passed through 'Sephadex *G*-100' columns (1 cm × 20 cm) to remove radioactive substrates. The labelled RNA preparations were hydrolysed with pancreatic ribonuclease, and the resulting radioactive fragments were separated by 'DEAE-Sephadex' column chromatography according to the procedure previously described[8]. Values are expressed in per cent.

Table 4. HYBRIDIZATION TESTS WITH RNA SYNTHESIZED BY RNA POLYMERASE WITH AND WITHOUT σ-FACTOR

DNA	C.p.m. hybridized* Core	Core + σ-factor
Denatured calf thymus DNA	32	10
Denatured RF DNA	572	623
Single stranded DNA from mature phage	256	25

* Average of two experiments.

For the preparation of ^{3}H-RNA, the reaction mixture (1 ml.) contained 40 mM Tris-HCl (*p*H 7·9), 8 mM $MgCl_2$, 40 mM KCl, 0·4 mM each of CTP, UTP, GTP and ^{3}H-ATP (5,000 c.p.m./nmole), 10 μg RF-I DNA and 5 μg core enzyme. About 3 μg of σ-factor was added. Following incubation for 10 min at 37° C, 10 μg of pancreatic deoxyribonuclease was added, and the incubation was continued for an additional 10 min. The mixture was chilled, treated twice with 80 per cent phenol, and then passed through a 'Sephadex *G*-100' column (1 cm × 20 cm) equilibrated with 0·15 M NaCl 20 mM Tris-HCl (*p*H 7·9). The RNA fraction eluted was collected. For the hybridization tests, the mixtures contained, in a final volume of 1 ml., 0·5 M NaCl, 20 mM Tris-HCl (*p*H 7·9), about 2,000 c.p.m. ^{3}H-RNA, and either 10 μg single stranded DNA from mature phage fd or 20 μg denatured RF DNA (sonicated, heated at 100° C for 10 min and quickly cooled). As control, 20 μg of denatured calf thymus DNA was added in place of phage DNA. The mixtures were incubated for 30 min at 67° C and cooled to room temperature. Pancreatic ribonuclease (10 μg) was added. After 20 min at room temperature, the mixtures were diluted with 0·5 M NaCl, 20 mM Tris-HCl (*p*H 7·9), and passed through 'Millipore' filters (type *HA* 0·45 μm). The filters were washed twice with 5 ml. each of the same buffer, and bound radioactivity was determined.

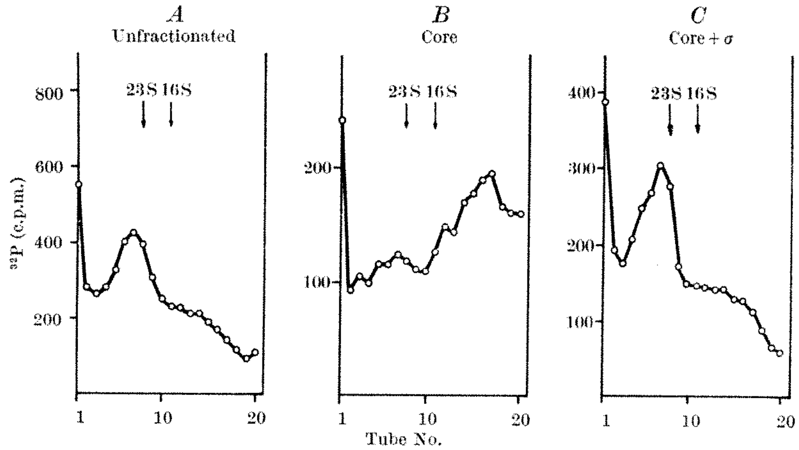

Fig. 3. Sedimentation analysis of RNA labelled with γ-^{32}P-ATP synthesized by RNA polymerase with and without σ-factor. The reaction mixture (1 ml.) contained 40 mM Tris-HCl (*p*H 7·9), 8 mM $MgCl_2$, 40 mM KCl, 0·2 mM each of CTP, GTP, UTP and γ-^{32}P-ATP (10^6 c.p.m./nmole), 20 μg RF-I DNA and (*A*) 10 μg undissociated enzyme, (*B*) 3 μg core enzyme, and (*C*) 3 μg core enzyme + 2 μg σ-factor. After incubation for 10 min at 37° C, the reaction was terminated by chilling. The reaction mixtures were treated with 80 per cent phenol, and then passed through 'Sephadex *G*-100' columns (1 cm × 20 cm). To the RNA fraction eluted, *E. coli* ribosomal RNA was added as marker. The mixtures were placed on sucrose density gradients (5 to 20 per cent in 0·15 M NaCl–20 mM Tris-HCl, *p*H 7·9) formed in Spinco *SW*25 tubes. After centrifugation for 16 h at 25,000 r.p.m. and 5° C, drops were collected from the tube bottom. The radioactivity and absorbance at 260 nm were determined. The arrows in figures indicate the positions of *E. coli* ribosomal RNA.

enzyme, the major peak was again found at the 26S region (Fig. 3*C*). The core enzyme therefore seems to initiate RNA synthesis at random along the template.

Role of σ-Factor in Transcription on RF-I DNA

The primary reactions involved in the initiation of RNA synthesis are the association of RNA polymerase to the promotor sites of the template, and the binding of the initiating ATP or GTP to the DNA–enzyme complex. Like the complete enzyme, the core enzyme alone initiated RNA synthesis with purine nucleoside triphosphates. The RNA synthesized in the absence of σ-factor was, however, very heterogeneous both in size and in the character of the initiating nucleotide sequences. It was also shown that the core enzyme transcribed both strands of the template. Addition of σ-factor to the core enzyme restored the specificity of the enzyme so that it transcribed the minus strand of the template at limited regions.

These observations would imply that the core enzyme has an intrinsic ability to initiate RNA synthesis with purine nucleoside triphosphates by associating with the template. The function of the σ-factor seems to be the prevention of random initiation by the core enzyme and the selection of promotor sites at which synthesis of "sense" RNA is initiated. A similar conclusion has been advanced by Bautz *et al.*[6], who demonstrated that the σ-factor selectively stimulated the transcription of a group of T4 genes which are expressed *in vivo* immediately after infection.

Questions remain concerning the configuration of DNA forming the promotor sites and how these sites are recognized preferentially by RNA polymerase containing σ-factor. It should be mentioned that the σ-factor loses its specificity after storage, though still retaining its ability to stimulate incorporation significantly.

We thank Dr J. S. Krakow, of the University of California, for his interest and for reading the manuscript.

Prostaglandins E_1, E_2, $F_{2\alpha}$ and A_2 are enzymically inactivated to different extents during passage through the pulmonary circulation. The enzyme responsible is probably 15-hydroxyprostaglandin dehydrogenase.

Ferreira and J. R. V.[1] discovered that the activity of prostaglandins E_1 and E_2, although stable in blood, almost completely disappeared in a single transit through the pulmonary circulation of dogs, cats and rabbits. This work has now been confirmed and extended by several workers; prostaglandins E_1, E_2 and $F_{2\alpha}$ are almost completely inactivated by the pulmonary circulation of cat, dog, rat and guinea-pig[2-5]. In contrast, the vasodilator activity of prostaglandins A_1 and A_2 survives passage through the pulmonary circulation of the cat and dog[3,4].

The mechanism by which the lungs inactivate prostaglandins has not been defined; this might be by uptake into cells in the lungs, uptake into blood cells or chylomicrons as these pass through the capillaries, binding to plasma proteins, or metabolism. Samuelsson *et al.*[6-9] demonstrated the presence of 15-hydroxyprostaglandin dehydrogenase in lung homogenates and we have now found that the prostaglandins are enzymatically inactivated as they pass through the pulmonary circulation. We have also compared the rates of metabolism for prostaglandins E_1, E_2, $F_{2\alpha}$ and A_2.

Two Types of Experiments

Guinea-pigs (0·5–1·2 kg) of either sex were killed and their heart and lungs were excised. A polyethylene cannula was inserted through the right ventricle into the pulmonary artery and the lungs were perfused with Krebs solution supplied at 10 or 20 ml./min by a roller pump. The Krebs solution was previously gassed with 5 per cent carbon dioxide in oxygen and was warmed to 37° C by a water jacket, except in three experiments in which the temperature was varied. The lungs were initially inflated with air through a cannula in the trachea; this helped to flush out all the visible blood.

The first of the two types of experiments were single pass experiments. In these a known concentration of a prostaglandin was added to the Krebs solution entering the lungs and the prostaglandin emerging in the venous effluent was estimated by bioassay. In some experiments the bioassay was made continuously by superfusing the effluent from the lungs over various tissues[10,11]—a rat stomach strip[12], a rat colon[13] and a chick rectum[14]. In other experiments the venous effluent from the lungs was sampled serially and each sample was then assayed for prostaglandin content on a rat stomach strip suspended in a 5 ml. organ bath, or on a series of organs superfused with Krebs solution. The second type of experiment involved recycling 50 or 100 ml. of Krebs solution (gassed with 5 per cent carbon dioxide in oxygen) from a small reservoir through the lungs for up to 30 min. Inactivation of prostaglandins added to the reservoir was estimated by assay of 1 ml. samples removed from the reservoir at various times.

Samples of perfusate were also collected for examination by thin-layer chromatography on silica gel *G* with the A II or A III solvent systems of Samuelsson *et al.*[6,15].

In twenty-five pairs of guinea-pig lungs prostaglandins were infused into the pulmonary artery and the effluent superfused over assay tissues. The disappearance of prostaglandins E_2, $F_{2\alpha}$ and A_2 in the pulmonary circulation was estimated by comparing the responses of the assay organs to infusions given into the pulmonary circulation or directly to the assay organs (Table 1). With prostaglandin E_2 (0·05–0·5 μg/ml.) a mean of 92 per cent disappeared in one transit through the pulmonary circulation (Fig. 1) and the disappearance was not related to the dose (fourteen experiments). With prostaglandin $F_{2\alpha}$ (0·1–1 μg/ml., six experiments), 90 per cent disappeared in the pulmonary circulation, and with prostaglandin A_2, 64 per cent (0·1–0·2 μg/ml., five experiments).

Recovery of Prostaglandins from Guinea-pig Lungs

To find out whether the prostaglandins which disappeared in the lungs were stored in some way, four pairs of perfused lungs were homogenized in ethanol and extracted. After thin-layer chromatography using the A II solvent system, material was recovered from consecutive regions of the thin-layer plates and resuspended in Krebs solution. Prostaglandins were then estimated on a rat stomach strip and a rat colon. Three of the pairs of perfused lungs had caused the disappearance of about 50 μg E_2, 50 μg $F_{2\alpha}$ and 50 μg E_2 + 50 μg $F_{2\alpha}$ respectively. The quantities of prostaglandin $F_{2\alpha}$ recovered were 200, 210, 100 ng (25, 25 and 13 ng/g wet weight), and of prostaglandin E_2, 125, 50, 160 ng (10, 6 and 20 ng/g wet weight).

The fourth pair of lungs was perfused with Krebs solution without addition of prostaglandins. The left and right lungs were processed separately and prostaglandin E_2 (equivalent to 1 μg/g) was added to one extract at the initial homogenization. Forty-two per cent of this added prostaglandin was recovered in the final assay. The other lung, to which no prostaglandin had been added, yielded prostaglandin E_2 at a concentration of 10 ng/g. These results showed that the prostaglandins which disappeared in the lungs were not taken up and stored.

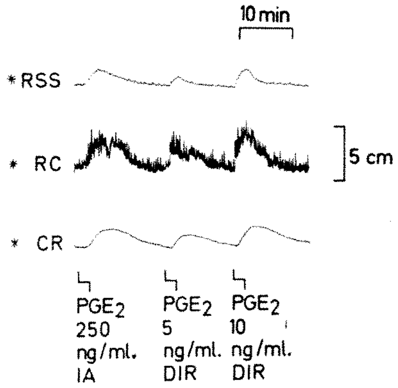

Fig. 1. Contractions of a rat stomach strip (RSS), rat colon (RC) and chick rectum (CR) superfused with Krebs solution after it had passed through lungs from an unsensitized guinea-pig. The contractions of the assay organs during infusion of prostaglandin E_2 (PGE_2) into the pulmonary artery (IA) were bracketed by contractions caused by infusions of PGE_2 5 and 10 ng/ml. given directly to the assay tissues (DIR). This shows that 96 per cent of PGE_2 was removed in the pulmonary circulation. Time scale 10 min; vertical scale 5 cm.

Evidence that the Lungs metabolize Prostaglandins

Guinea-pig lungs were perfused with Krebs solution from a reservoir and the venous effluent was returned to the reservoir. When prostaglandins were added to this recycling system, large quantities disappeared in a short time. This is shown in Fig. 2, which is a tracing of contractions of a rat stomach strip superfused with Krebs solution. The strip was sensitive to 10 or 20 ng of prostaglandin E_2 (end panels), but Krebs solution alone from the perfused lungs was inactive in a dose of 0·5 ml. Prostaglandin E_2 (1 μg/ml.) was then added to the circuit. Samples of 0·05 ml. of the recycled Krebs solution now showed activity. This activity declined to a low level within 15 min after which the residual activity (tested in 0·5 ml. samples) no longer declined. That this residual activity was due to a metabolite of prostaglandin E_2 was shown by recycling 50 μg of prostaglandin E_2 through perfused lungs for 30 min. Prostaglandins were then extracted from the Krebs solution and were submitted to thin-layer chromatography on the A III system. Prostaglandins recovered from the thin-layer plate by elution into methanol were resuspended in Krebs solution after evaporation of the methanol *in vacuo*. Bioassay then showed two peaks

Parentheses indicate weak spots.

The metabolism of prostaglandins in perfused lungs from the guinea-pig was temperature dependent, as shown in Fig. 4. A rat stomach strip and a rat colon, superfused with Krebs solution at 37° C, were calibrated by injections of prostaglandin E_2 (10–100 ng). A pair of guinea-pig lungs were also perfused with Krebs solution at 20 ml./min from a reservoir of 100 ml.; the venous effluent was recycled and the whole system was kept at 6° C. The contractions of the assay tissues, induced by 0·5 or 0·05 ml. of Krebs solution assayed immediately after withdrawal from the lung circuit, indicate the time course of decay of prostaglandin E_2 added to the circuit. The activity remained constant while the lungs were kept at 6° C, but when the circuit was quickly warmed to 37° C the prostaglandin activity disappeared in about 10 min. A second experiment at 6° C gave a similar result and in a third at 14° C the metabolism of prostaglandin E_2 was greatly slowed.

Chromatography of Metabolites

Prostaglandins (200 or 500 ng/ml.) were either passed once through the isolated lungs (two experiments) or recycled for 20 min (initial concentration of 1 µg/ml., three experiments). The Krebs solution in the venous effluent or in the reservoir was then extracted into small volumes of methanol and submitted to thin-layer chromatography on silica gel *G* with the A III solvent. After developing the chromatograms for a distance of 13 cm, the plates were dried in air and sprayed with phosphomolybdic acid (10 per cent in ethanol) and heated in a hot air oven at 120° C for 20 min. Prostaglandins appeared as bluish-grey spots and were detected in all five experiments, provided that at least 10 µg prostaglandin or its metabolite had been applied to the plate. As well as staining added prostaglandins, phosphomolybdic acid stained a considerable quantity of material from recycled Krebs solution when no prostaglandin had been added. The bulk of this unidentified material ran near the solvent front. It was present in extracts of untreated Krebs solution, so it did not originate in the lungs. Added prostaglandins, however, were detectable against this background (Table 2). Prostaglandin E_2 showed as a dense compact spot with an R_F of 0·16 (range 0·13–0·22). Prostaglandin A_2 was similarly obvious, with an R_F of 0·51 (range 0·48–05·5). Prostaglandin E_2 also gave a weak spot at R_F 0·55. This was seen when prostaglandin E_2 was chromatographed by itself (experiment 7, Table 2) as well as in other experiments in which it was extracted from Krebs solution and chromatographed (experiments 1 and 4 of Table 2). This suggests that the prostaglandin E_2 sample was contaminated with prostaglandin A_2.

Chromatography of the extracts after the prostaglandins had passed through the pulmonary circulation gave a different picture. The spots due to prostaglandin E_2 vanished and were replaced by two new spots ($R_F = 0·43$ and 0·78). The slower moving of these two metabolites of prostaglandin E_2 was not prostaglandin A_2, for it had a lower mobility in experiments 4 and 5 of Table 2. Besides, prostaglandin A_2 also disappeared in the lungs and was replaced by a metabolite which ran nearly to the solvent front (R_F 0·78). We were thus unable to decide whether the faster moving metabolite was derived from prostaglandin E_2 itself or from traces of prostaglandin A_2. As with prostaglandins A_2 and E_2, prostaglandin $F_{2\alpha}$ was

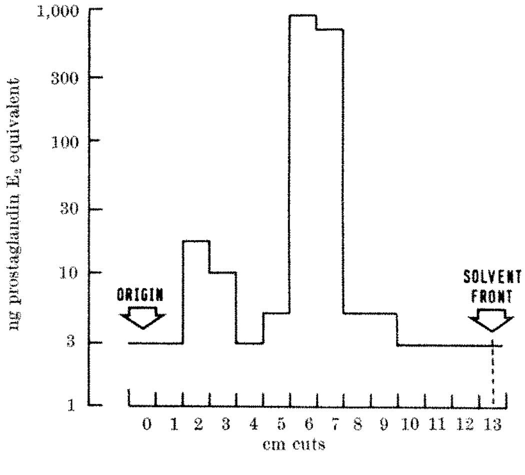

Fig. 3. Chromatography of prostaglandins. Prostaglandins were extracted from Krebs solution which had originally contained 50 µg E_2 in the recycling system and submitted to thin-layer chromatography in the A III solvent system. Centimetre cuts were made in the silica gel from the origin to the solvent front (horizontal scale). Prostaglandins were recovered by elution with methanol and estimated by bioassay in terms of prostaglandin E_2 equivalent (vertical scale). The first peak (R_F 0·18) corresponds to prostaglandin E_2 and the second (R_F 0·50) to its metabolite.

transformed into a less polar metabolite (R_F 0·17). We have not identified any of these metabolites except to show that neither prostaglandin E_2 nor A_2 is metabolized to prostaglandin A_1, A_2, E_2 or $F_{2\alpha}$.

Samuelsson *et al.*[6,16,17] have elucidated the structures of metabolites of E-type prostaglandins which were formed by enzyme systems found in the high speed supernatant of homogenates of guinea-pig lung. The two metabolites of prostaglandin E_2 had R_F values in the A III system of 0·32 (metabolite I) and 0·65 (metabolite II) while that of prostaglandin E_2 was 0·14. Thus although we obtained a similar R_F for prostaglandin E_2 there is a discrepancy between these values and those for the metabolites we obtained (R_F 0·43 and 0·78). This may be because of differences in chromatographic conditions, or may indicate that metabolites produced by intact lungs are different from those produced by homogenized tissue.

Rapidity of Metabolism

The rapidity of metabolism and completeness of inactivation of prostaglandins by the lungs are of importance. If, in a single transit, the prostaglandins are almost completely inactivated at all concentrations which might be encountered in life, it is unlikely that they have a function as circulating hormones. It has long been known that extracts of renal medulla contain vasodepressor substances identified as prostaglandin E_1 (refs. 18 and 19), as prostaglandin E_2 (ref. 20), as prostaglandin A_2 (ref. 21), and as a mixture of prostaglandins E_2, $F_{2\alpha}$ and A_2 (ref. 22) with some evidence that the A_2 was formed from E_2 during extraction procedure. In the cat and dog, the vasodilator activity of prostaglandin A_1 and A_2 passes the lungs without being decreased[3,4]. We have now compared the rate of inactivation of prostaglandin A_2 with that for prostaglandin E_1, E_2 and $F_{2\alpha}$ in perfused lungs from the guinea-pig. This was done in two ways. In the first, known concentrations of prostaglandins were infused into guinea-pig lungs and the activity leaving the lungs was estimated by the contractions of superfused tissues. The results of these experiments are shown in Table 1; inactivation of prostaglandin A_2 is clearly less than that of prostaglandin E_2. This difference could be due to a substantial fraction of prostaglandin A_2 evading metabolism, or it could be due to its complete transformation to metabolites which were still active biologically. The second type of experiment was designed to investigate the extent to which each of these mechanisms contributed to the results.

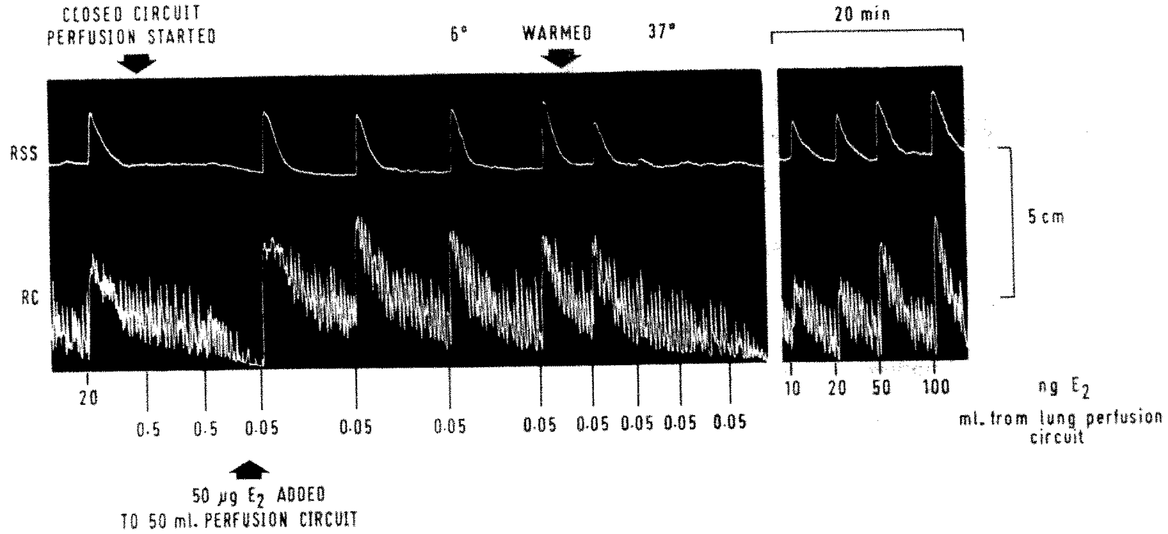

Fig. 4. Contractions of a rat stomach strip (RSS) and a rat colon (RC) superfused with Krebs solution. 50 ml. of Krebs solution was recycled through a pair of guinea-pig isolated lungs. Samples of 0·5 or 0·05 ml. of this solution were withdrawn and immediately assayed for prostaglandin content on RSS and RC. The recycling system was initially kept at 6° C and 50 µg E_2 added to the Krebs. The recycling Krebs was later warmed to 37° C. The prostaglandin content of the recycling Krebs solution changed little at 6° C but declined rapidly when the system was warmed to 37° C. Horizontal scale 20 min; vertical scale 5 cm.

In recycling experiments a known quantity of prostaglandin was added to the system and samples were removed at intervals thereafter. These were subsequently assayed against standard prostaglandins on a rat stomach strip in a 5 ml. bath. This system should produce an exponential decay of prostaglandin activity if the lungs metabolize a constant proportion of prostaglandin passing through them for widely different concentrations. We have not found clear evidence that the lungs depart from this behaviour, even with starting concentrations as high as 2·5 µg/ml. This implies that the enzyme systems are not saturated by these high concentrations. Fig. 5 shows the result of such an experiment (Table 2, experiment 3) in which prostaglandin A_2 (1·0 µg/ml.) was added to the 50 ml. circuit and observations were made for 15 min. After lung perfusion for 10 min with fresh Krebs solution, a second recycling experiment was performed using prostaglandin E_2 (1·0 µg/ml.). Fig. 5 shows plots of log N/N_0 against time for these two experiments (N = prostaglandin activity at time t; N_0 = prostaglandin activity corresponding to 1·0 µg/ml.). Regression lines were drawn by the method of least squares. The slope of each line, multiplied by 2·3, gives k in the expression $N = N_0e^{-kt}$. The value for k depends on the percentage of prostaglandin inactivated in a single passage through the lungs. In this experiment $k = 0·51$ corresponds to 100 per cent inactivation of prostaglandin in a single passage through the lungs, and $k = 0·088$ corresponds to 23 per cent inactivation.

This method also allowed measurement of residual activity after recycling the Krebs solution for 30 min. Whereas prostaglandin E_2 activity declined to 0·7–3·2 per cent of the original level, that of prostaglandin A_2 ceased to decline when it reached about 25 per cent of the original activity (Table 3). Making allowance for this residual activity which we assume represents the bioactivity of the metabolite(s), it is possible to calculate the percentage metabolism of A_2 in a single transit of the lungs (Table 3). It appears that prostaglandin A_2 is metabolized at a slower rate than E_1, E_2 or $F_{2\alpha}$.

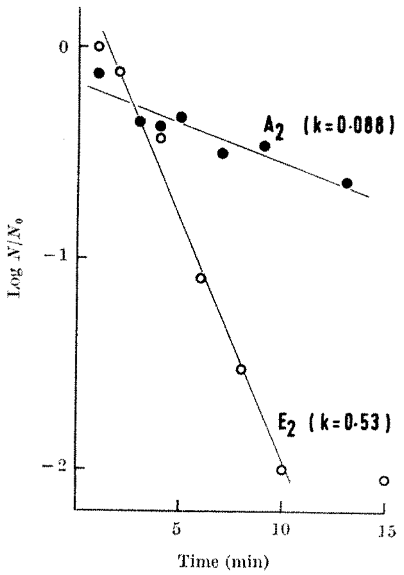

Fig. 5. Inactivation of prostaglandins A_2 (A_2) and E_2 (E_2) by guinea-pig lungs (from experiment 3, Table 3). Prostaglandin A_2 (1·0 μg/ml.) was added to a 50 ml. recycling system and the change in concentration during repeated passage through the pulmonary circulation estimated by assay on a rat stomach strip. After perfusing the lungs with fresh Krebs solution for 10 min, the experiment was repeated using prostaglandin E_2 (1·0 μg/ml.). N = Prostaglandin activity at time t. N_0 = Prostaglandin activity corresponding to 1·0 μg/ml. The slope of each line, multiplied by 2·3, gives k in the expression $N = N_0e^{-kt}$. The value for k depends on the percentage of prostaglandin inactivated in a single passage through the lungs. In this experiment $k = 0·51$ corresponds to 100 per cent inactivation and $k = 0·088$ corresponds to 23 per cent inactivation. Vertical axis log N/N_0 for A_2 and E_2; horizontal axis time in min.

Applying a similar correction to the data in Table 1, it is found that a mean percentage inactivation of 64 per cent for prostaglandin A_2 implies 84 per cent metabolism in a single transit of the lungs. This is still clearly less than that of prostaglandin E_2 ($P < 0·01$). Thus all the prostaglandins we studied underwent extensive metabolism in a single passage through the lungs. The apparently smaller effect on prostaglandin A_2 is due partly to the activity of the metabolite on the rat stomach strip, and partly to less avid metabolism of this prostaglandin by the lungs.

Table 3

Exp.	Prostaglandin (initial concentration, μg/ml.)	Volume (ml.)	Pump rate (ml./min)	k (min^{-1})	Calculated percentage inactivation in one pass	Observed final activity (at 30 min) (percentage of original)	Calculated percentage metabolized in one pass
1	E_2 (1·0)	100	20	0·23	102	1·0	103
	$F_{2}\alpha$ (2·0)	100	20	0·073	35	—	—
2	E_2 (1·0)	50	20	0·43	88	0·7	89
	E_1 (1·0)	50	20	0·46	92	1·8	94
	$F_{2}\alpha$ (1·0)	50	20	0·32	68	1·0	69
	E_2 (1·0)	50	20	0·36	76	0·9	77
3	A_2 (1·0)	50	20	0·088	23	23	30
	E_2 (1·0)	50	20	0·53	107	0·9	108
4	A_2 (2·5)	50	20	0·105	25	24	33
5	A_2 (2·5)	50	20	—	—	27	—

We conclude that the disappearance of the activity of prostaglandins in the pulmonary circulation is due to their metabolism to less polar derivatives. The products of the metabolism of prostaglandin E_1 and E_2 in cat, dog, rabbit and guinea-pig have insignificant activity on the rat stomach strip[1,5], on renal blood flow in the dog[3] or on blood pressure in cat or dog[4]. Prostaglandin $F_{2\alpha}$ is also metabolized, perhaps at a slightly slower rate. Its products in the dog are inactive on renal blood flow[3], and in the perfused guinea-pig lungs the products are inactive on the rat stomach strip, rat colon and chick rectum.

With prostaglandins A_1 and A_2, the situation is different. In the cat and dog, there is little or no change in vasodilator activity of prostaglandin A_1 and A_2 on passage through the lung[3,4]. Our results in the guinea-pig perfused lungs show 23–75 per cent inactivation of prostaglandin A_2 in one passage, as measured by activity on the rat stomach strip. Some of the residual activity was due to the metabolite(s); some was due to unchanged A_2. This suggests either that the guinea-pig isolated lungs behave differently from the lungs of the other two species, or that there is similar metabolism in cat and dog, but that the products have as potent a vasodilator activity as does prostaglandin A_2.

We did not identify the products of the metabolism of the prostaglandins, but the simplest explanation of our results is that the enzyme isolated from swine and guinea-pig lung, 15-hydroxyprostaglandin dehydrogenase[6–9], is responsible. The fact that this enzyme metabolizes A_1 and A_2 at a slower rate than E_1 and E_2 (refs. 6 and 7) fits with our results. The lack of correspondence between the R_F values of the metabolic products might have been due to different chromatographic conditions.

Our results support the previous conclusion[23] that the E-type prostaglandins are unlikely to be circulating hormones, but leave the possibility that A_1 and A_2 might be.

It is interesting to speculate on the possible role of the pulmonary circulation in control of blood pressure. In the case of the renin–angiotensin system the kidney secretes renin and angiotensin I is generated in the plasma; but it is the converting enzyme in the lungs[24–26] which brings about the release of the potent vasoconstrictor angiotensin II. If the kidneys are also able to secrete prostaglandin A_2 and if the lungs possess a mechanism to regulate the degree of metabolism of this substance, a comparable situation would exist for presenting a potent vasodilator substance to the arterial circulation.

We thank Miss Leslie Gruby and Mr M. A. Palmer for technical assistance and the MRC and Wellcome Trust for grants. We also thank Dr J. E. Pike of the Upjohn Company, Kalamazoo, for a gift of prostaglandins.

Novel Correlations between Global Features of the Earth's Gravitational and Magnetic Fields

by

R. HIDE

Meteorological Office,
Bracknell, Berkshire

S. R. C. MALIN

Institute of Geological Sciences,
Herstmonceux Castle, Sussex

There is a significant correlation between the Earth's gravitational field and the non-dipole part of the geomagnetic field, provided the latter is displaced in longitude.

It is more than forty years since seismological studies first revealed the existence of a liquid core within the Earth at depths greater than 2,900 km ($=0{\cdot}455\ R$ where $R=6{,}371{\cdot}2$ km is the Earth's mean radius), but little is so far known of the interface between the core and the overlying solid mantle[1], where there is a more or less abrupt change of density from 5·6 g cm^{-3} to 9·6 g cm^{-3}.

Undulations of the interface (bumps) on a planetary scale a few kilometres in vertical amplitude (and therefore well below the present limit of resolution by seismological methods) would, according to a recent suggestion[2,3], interact so strongly with fluid motions in the core as to produce significant distortions in the geomagnetic field **B** as measured at and near the Earth's surface (and to account for the horizontal stresses at the core–mantle interface that are implied by the most pronounced changes observed in the length of the day[4]). Such bumps would also distort the gravitational field **g**, contributing significantly to the low-order harmonics (of degree n less than 5 or 6) of **g** at the surface of the Earth[5].

Qualitatively, distortions in **B** could be displaced relative to the bumps through distances at least comparable with the horizontal scale of the bumps—thousands of kilometres. This suggests that the variation of the degree of correlation of **g** and **B** with the horizontal displacement of one field relative to the other is worth studying[2]. Attention is confined to displacements in longitude alone, a procedure which avoids the complications of transforming spherical harmonic series from one polar axis to another, but a physically reasonable one because core motions are probably mainly zonal[2]; this restriction should be relaxed in future work.

Spherical Harmonics and Truncation

The gravitational field of the Earth at a point with spherical polar coordinates (r, φ, λ) can be expressed in terms of spherical harmonics by introducing a potential U such that $\mathbf{g}=-\nabla U$, where[1,6,7]

$$U = \frac{MG}{R}\left\{\frac{R}{r} + \sum_{n=1}^{\infty}\sum_{m=0}^{n} S(A_n, A_n^m, B_n^m)\right\} + U_e \qquad (1)$$

Here r denotes distance from the Earth's centre of mass, φ co-latitude, λ east longitude, G is the universal gravitational constant, M is the total mass of material contained within a sphere of radius r centred on the origin of coordinates, U_e is the potential due to sources lying outside that sphere and $S(A_n, A_n^m, B_n^m)$ is a typical term in the spherical harmonic expansion of U (see appendix A for exact definition), where m denotes the order of the harmonic and n the degree, m and n being positive integers. A_n, A_n^m and B_n^m are coefficients appearing in S, which is also a function of $(R/r)^{n+1}$, $\cos m\lambda$, $\sin m\lambda$ and $\cos\varphi$. (The coefficients in the spherical harmonic expansion of the topography of the core–mantle interface[5] are, apart from an unimportant constant, the same as those in the expansion for $U-U_e$ evaluated at $r=0{\cdot}545\ R$.)

The main geomagnetic field in regions where local electric currents are negligible can be similarly expressed. Thus $\mathbf{B}=-\nabla V$ where[8,9]

$$V = \frac{L}{R^2}\sum_{n=1}^{\infty}\sum_{m=0}^{n} S(a_n, a_n^m, b_n^m) + V_e \qquad (2)$$

a_1L (see appendix A) being the resolute parallel to the Earth's rotation axis of the moment of the effective magnetic dipole component of sources within a sphere of radius r centred on the origin of coordinates and V_e is the potential due to magnetic sources lying outside the sphere. As magnetic materials in the Earth's mantle and crust[9,10], sources outside the Earth and very slight leakage of electric currents out of the liquid core into the solid mantle make an insignificant contribution to global-scale features of the main geomagnetic field, we can suppose that sources of V are largely confined to the core. Consequently equation (2) with $V_e=0$ should constitute a satisfactory representation of V throughout the mantle, including the extreme levels $r=0{\cdot}545\ R$ and $r=R$.

The main geomagnetic field **B**, unlike **g**, undergoes measurable fluctuations on time-scales of a few years and upwards[8,9]. The potential of the so-called "geomagnetic secular variation" may be expressed in terms of an expansion similar to equation (2) by changing V to $\dot{V}$ and (a_n, a_n^m, b_n^m) to $(\dot{a}_n, \dot{a}_n^m, \dot{b}_n^m)$, where the dot denotes differentiation with respect to time. A significant part of the geomagnetic secular variation can be represented in terms of a uniform westward drift[11-13] of the main geomagnetic field at $u_0=0{\cdot}0035$ rad yr^{-1} ($=0{\cdot}20$ degrees of longitude yr^{-1}). We may remove this part of the secular variation, thus leaving a (hypothetical) non-drifting part with coefficients (α_n^m, β_n^m), where

$$\alpha_n^m = \dot{a}_n^m - u_0 m b_n^m,\ \beta_n^m = \dot{b}_n^m + u_0 m a_n^m \qquad (3)$$

Global-scale features of U and V are described by the foregoing series truncated at some low value n^* of n. We take $n^*=4$ in the first instance, for reasons given in the previous section, before examining systematically the sensitivity to the value chosen for n^* of the principal results obtained.

Because the coordinate system for gravitational measurements has its origin at the Earth's centre of mass and the Earth rotates about its axis of maximum moment of inertia, the terms A_1, A_1^1, B_1^1, A_2^1 and B_2^1 are all zero[6]. Thus, we are left with A_2^2, B_2^2, A_3^1, B_3^1, A_3^2, B_3^2, A_3^3, B_3^3, A_4^1, B_4^1, A_4^2, B_4^2, A_4^3, B_4^3, A_4^4 and B_4^4. Corresponding to this set of sixteen (equals $n^*(n^*+1)-4$) coefficients required to specify the tesseral part of the spherical harmonic series for U truncated at $n=n^*=4$, we have sets for V and $\dot{V}$, respectively the potentials of the geomagnetic field and the geomagnetic secular variations, and for the non-drifting part of the secular variation (see equation (3)).

Correlation Coefficients

One method of investigating correlations between U and V is to evaluate grid-point values (at the level

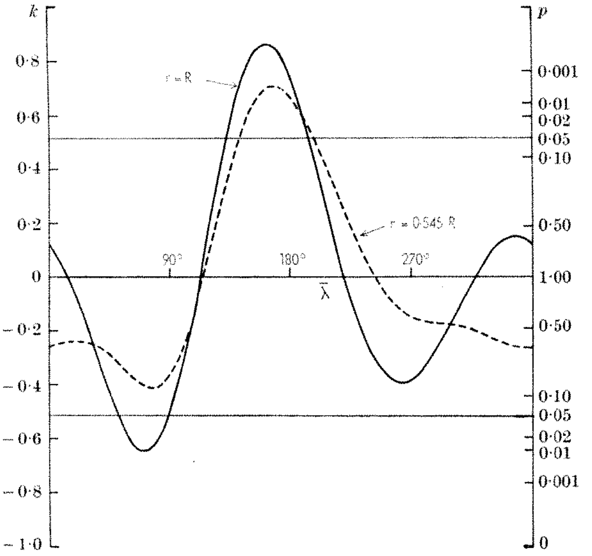

Fig. 1. The dependence of the degree of correlation k between the large-scale features of the non-dipole part of the Earth's magnetic field, **B**, for epoch 1965 and gravitational field, **g**, as described by spherical harmonic coefficients of degree not greater than 4, on the eastward displacement in longitude of **B** relative to **g** through an angle $\bar{\lambda}$. A value of unity for k would correspond to perfect correlation. The solid curve corresponds to the fields at the Earth's surface and the broken curves to hypothetical fields obtained by extrapolating the surface spherical harmonics down to the level $r = 0{\cdot}545R$. On the Student t test (see significance levels p given at the right-hand side of the diagram), the odds that the maximum value of k, found at $\bar{\lambda} = 160°$, represents a true physical connexion between **B** and **g** exceed 1,000 : 1. When deficiencies in the Student t test are taken into account (see text) the odds are lower, 100 : 1, but still well within the generally accepted limit of significance (20 : 1).

required, surface or core–mantle boundary) and calculate correlation coefficients from these (indeed, contingency tests along these lines were carried out as a preliminary to the present work). But because we are representing U and V by spherical harmonic series we can estimate correlation coefficients k at $r = R$ directly in terms of the coefficients (a_n^m, b_n^m) and (A_n^m, B_n^m), by means of equation (B1) (see appendix B). That equation applies when $\bar{\lambda}$, the eastward displacement of V relative to U, is zero; when $\bar{\lambda} \neq 0$ the coefficients a_n^m and b_n^m should be changed as follows:

$$(a_n^m, b_n^m) \longrightarrow ([a_n^m \cos m\bar{\lambda} - b_n^m \sin m\bar{\lambda}], \quad [b_n^m \cos m\,\bar{\lambda} + a_n^m \sin m\bar{\lambda}]) \qquad (4)$$

To find k at other levels $r \neq R$ where no sources of tesseral harmonics are present, (a_n^m, b_n^m) and (A_n^m, B_n^m) should be multiplied by $(R/r)^{n+1}$.

Values of k have been calculated for $\bar{\lambda} = 0°$ to $360°$ at 2° intervals and for two values of r/R, namely 1·000 and 0·545 (see Fig. 1), using coefficients given by various workers (see Table 1); the principal results are summarized in Table 2.

At epoch 1965 the maximum degree of correlation, coefficient $\hat{k}$, of the gravitational field with the displaced magnetic field occurs when $\bar{\lambda}$ has the value $\hat{\lambda} = 160°$ (see the section on drift of the geomagnetic field). $\hat{k}$ and $\hat{\lambda}$ are apparently insensitive to the particular field models chosen (the variations between models being slightly greater for U than for V). Thus we need only discuss one pair of models and "CA" for U and "LME" for V (see Table 1) are chosen. The corresponding values of $\hat{k}$ and $\hat{\lambda}$ at $r = R$ are 0·8381 and 160° respectively (see Fig. 1). That this value of $\hat{k}$ represents a statistically significant correlation will be demonstrated in the next section. Tables 1 and 2 also show that $\hat{k}$ is a good deal less for the secular variation than for the geomagnetic field itself. In all cases (except the non-drifting geomagnetic secular variation) $\hat{k}$ is larger at $r = R$ than at $r = 0{\cdot}545\ R$.

As an additional exercise the correlation between $|U|$ and $|V|$ was investigated. In this case it was not possible to work with spherical harmonic coefficients directly, so 10° × 10° grid point values were synthesized at $r = R$ and $r = 0{\cdot}545\ R$ and k investigated as a function $\bar{\lambda}$, as before. The results are shown in Table 3.

For the case of the magnetic field, taking the modulus makes little difference to $\hat{k}$ and $\hat{\lambda}$; inevitably $\hat{k}$ must be larger when moduli are considered, but it is not much larger. The greatest effect of taking moduli occurs for the non-drifting secular variation, but, even so, $\hat{k}$ does not in this case attain a statistically interesting value.

Significance Tests

The next step is to compare the values of $\hat{k}$ found in the analysis (see Fig. 1 and Table 2) with those expected by pure chance and thus evaluate the extent to which the results must be regarded as evidence for a true physical association between the magnetic and gravitational fields. It is instructive to apply first the Student t test before considering complications due to factors that might invalidate the test.

Because we are considering 16 $(= n^*(n^* + 1) - 4)$ independent pairs of quantities we have $N = 16$ degrees of freedom when $\bar{\lambda}$ is fixed, but we lose one of these, so that $N = 15$, when we allow $\bar{\lambda}$ to vary. The t test is applied by calculating the quantity

$$t = k/[(1 - k^2)/(N - 2)]^{\frac{1}{2}} \qquad (5)$$

Table 1. POTENTIAL MODELS USED IN THE CORRELATION INVESTIGATION

Gravity	
GN	Guier and Newton[14]. Gravity potential deduced from doppler tracking of 5 satellites. Coefficients up to $m = n = 8$. These coefficients must be divided by $(4n + 2)^{1/2}$ to correct them to the fully normalized form.
G8	Gaposhkin[15]. Gravity potential from Baker–Nunn observations of 13 satellites. 98 coefficients; complete up to $m = n = 8$. Fully normalized. Kaula[16] considers this to be the best single solution.
K8	Kaula[16]. Gravity potential. 72 coefficients; complete up to $m = 5$, $n = 7$. Fully normalized.
C	Kaula[16]. Gravity potential. Arithmetic mean of Anderle[17], GN, K8 and Gaposhkin G6 (ref. 15) (all based on satellite data). 42 coefficients; complete up to $n = 7$, $m = 2$. Fully normalized. Better than any individual model[16].
CA	Kaula[16]. Gravity potential from C (above) and gravimetry. 42 coefficients; complete up to $n = 7$, $m = 2$. Fully normalized. Should be the best overall representation.
Magnetic Main Field	
LME	Leaton, Malin and Evans[18]. Magnetic potential deduced from surface and airborne observations. 80 coefficients; up to $m = n = 8$. Earth assumed to be spherical. Coefficients in Schmidt quasi-normalized form, must be divided by $(2n + 1)^{1/2}$ to correct them to the fully normalized form.
M IGRF	Malin[19]. Magnetic potential deduced from surface, airborne and satellite observations. 80 coefficients up to $m = n = 8$. Earth assumed to be an oblate spheroid. Coefficients in Schmidt quasi-normalized form.
C IGRF	Cain[20]. Magnetic potential deduced from surface, airborne and satellite observations. 120 coefficients, in Schmidt quasi-normalized form, up to $m = n = 10$. Earth assumed to be an oblate spheroid.
F IGRF	Fougère[19]. Magnetic potential, data unspecified. 120 coefficients, in Schmidt quasi-normalized form, up to $m = n = 10$. Earth assumed to be an oblate spheroid.
O IGRF	Orlov[21]. Magnetic potential deduced from Cosmos 49 total field observations. 48 coefficients, in Schmidt quasi-normalized form, up to $m = n = 6$. Earth assumed to be an oblate spheroid.
Magnetic Secular Variation	
M SV	Malin[22]. Magnetic secular variation potential deduced from observatory data, 1940–1965. 48 coefficients, in Schmidt quasi-normalized form, up to $m = n = 6$. Earth assumed to be spherical.
Magnetic Non-drifting Secular Variation	
M NDSV	Malin (unpublished). Magnetic secular variation after removal of the part which would arise from a westward drift of the main field of 0°·2 yr^{-1}. Deduced from M SV and main field coefficients deduced from the same set of observatory data[21].
N NDSV	Nagata[13]. Similar to M NDSV. The secular variation model was that of Nagata and Syono[23]; the main field model was that of Nagata and Oguti[24].

The four magnetic main field models denoted IGRF are those from which the International Geomagnetic Reference Field[25] was derived.

Table 2. CORRELATION BETWEEN GRAVITATIONAL POTENTIAL AND RECENT MAGNETIC POTENTIAL EVALUATED AT $r = 0·545\ R$ AND $r = R$

The numbers are arranged as follows: A $\begin{matrix} \text{C} \\ \text{B} \\ \text{D} \end{matrix}$

where A is the maximum correlation coefficient, $\hat{k}$,

B is the eastward displacement in longitude at which $\hat{k}$ occurs ($\hat{\lambda}$), to the nearest even degree,

C is the smallest value of $\bar{\lambda}$ for which the correlation coefficient exceeds 0·5139 (corresponding to the 5 per cent significance level, judged by the Student t test), to the nearest odd degree,

and D is the largest value of $\bar{\lambda}$ for which the correlation coefficient exceeds 0·5139, to the nearest odd degree.

and finding the significance level for t and N from standard tables[26,27]. Alternatively, we may reverse the procedure and find what value of k is likely to arise from a random set of data for a chosen significance level when $N = 15$.

Significance level	0·50	0·10	0·05	0·02	0·01	0·001
k	0·189	0·4409	0·5139	0·5923	0·6411	0·761

These significance levels are indicated in Fig. 1 and the values of $\bar{\lambda}$ at which k enters and leaves the 5 per cent significance level are given in Table 2.

The maximum correlation coefficient for the case $r = R$ illustrated in Fig. 1 is apparently significant at the 0·1 per cent level; $\hat{k}$ at $r = 0·545\ R$ is apparently significant at the 1·0 per cent level. These levels fall within the 5 per cent limit, so that if the t test is applicable then the corresponding values of $\hat{k}$ must be considered physically significant. The test may not be applicable here, however, and therefore the results of its application represent no more than a *prima facie* case for carrying out more stringent tests.

Suppose we are correlating two sets of data where the spherical harmonic coefficients are all zero except for a single pair of values of (m, n). By a suitable choice of $\bar{\lambda}$ we could then produce a value 1·0 for $\hat{k}$ (see, for instance, Table 4), apparently indicating perfect correlation. In the more realistic case when one value of

$$[(a_n^m)^2 + (b_n^m)^2]^{1/2}\ [(A_n^m)^2 + (B_n^m)^2]^{1/2}$$

Table 3. CORRELATION COEFFICIENT FOR RECENT EPOCH DEDUCED FROM SYNTHETIC GRID POINT VALUES

	Gravity model CA				
Magnetic model	Signed grid-point values		Modulus of grid-point values		r/R
	$\hat{k}$	$\hat{\lambda}$	$\hat{k}$	$\hat{\lambda}$	
M IGRF	0·8405	160°	0·8642	160°	1·000
	0·6383	170	0·7561	180	0·545
M SV	0·7483	200	0·7864	200	1·000
	0·4766	200	0·6999	30	0·545
M NDSV	−0·3952	310	0·7003	200	1·000
	0·4762	140	0·7402	130	0·545

is much larger than the other non-zero values we would still expect a very large, but probably spurious, value of $\hat{k}$.

A test in which this difficulty is recognized, which not only provides a more robust test than the t test but also permits an evaluation of the dependence of the degree of correlation on the largest terms in the original sets of coefficients, has been proposed by Brier (private communication, see appendix C). For the correlation between the gravitational and magnetic fields at $r=R$ using the "CA" model for U and the "LME" model for V (see Table 1), for which $\hat{k}=0\cdot8381$ and $\hat{\lambda}=160°$ (and the t test indicates a highly significant correlation, $p<0\cdot001$ where p is the probability that the data are uncorrelated), Brier's test gives $y=-2\cdot58$ and $p=0\cdot01$, where y is the weighted standard deviate (see equation (C6)), which is still well within the 5 per cent limit. The correlation is significant at the 5 per cent level when $\bar{\lambda}$ lies between 150° and 170°, but not otherwise. If we remove the pair of harmonics that make the largest contribution to the correlation coefficient, for which $(m, n)=(1,3)$, and repeat Brier's test using the same value of $\bar{\lambda}$, the correlation is still significant at the 3·4 per cent level (that is, $p=0\cdot034$, $y=-2\cdot12$). Only when the two largest pairs of harmonics, for which $(m, n)=(1,3)$ and $(1,4)$, are removed does p rise to a level bordering on insignificance (namely, 0·083, corresponding to $y=-1\cdot74$).

A high degree of correlation is thus established between those parts of the Earth's gravitational and non-dipole magnetic fields for epoch 1965 described by tesseral harmonics of degree $n\leq 4$ when the magnetic pattern is displaced 160° to the east but not otherwise. This correlation apparently stands up well to severe significance tests and therefore requires an explanation in geophysical terms. The harmonics used are all well determined, as shown by the consistency between models, and our results are unlikely to be affected substantially by new data or methods of analysis. For reasons that are not very clear (having regard for the arguments that prompted the investigation) the correlation is not quite so high at the core–mantle boundary.

Though less notable, a correlation is also established between gravity and the geomagnetic secular variation. This result is undoubtedly associated with the remarkably good correlation between the geomagnetic field and the geomagnetic secular variation, which was discovered incidentally during this investigation but will be discussed elsewhere.

Table 4 summarizes the results of an investigation of how the truncation procedure affects $\hat{k}$ and $\hat{\lambda}$ at $r/R=1$ and $r/R=0\cdot545$ for epoch 1965, carried out after the foregoing results for $n^*=4$ had been obtained. For this purpose it was convenient to use model G8 for the gravitational field, considered by Kaula[16] to be the best single solution, and model IGRF[25] for the magnetic field, both of which are complete up to $n=8$. The number of coefficients needed to represent each field, $n^*(n^*+1)-4$, increases rapidly with n^*, but because the coefficients fall off in amplitude with increasing n^*, it is not surprising to find at $r=R$ that $\hat{k}$ does not differ significantly from 0·8, $\hat{\lambda}$ does not differ materially from 160° at this epoch.

It is perhaps worth pointing out that if the correlation is caused by processes at the core–mantle interface, then there is no physical reason for expecting terms beyond $n=5$ or 6 to contribute to the correlation coefficient[5]; the high-degree terms in the gravitational field almost certainly originate in the upper part of the mantle.

Table 4. VARIATION OF $\hat{k}$ AND $\hat{\lambda}$ WITH n^* FOR EPOCH 1965

n^*	$\hat{k}(r/R=1)$	$\hat{\lambda}(r/R=1)$	$\hat{k}(r/R=0\cdot545)$	$\hat{\lambda}(r/R=0\cdot545)$

17[29]	1955	0·8354	158·8	−0·2
18[22]	1957·5	0·8344	159·7	0·1
19[20]	1960	0·8409	159·7	−0·6
20[22]	1962·5	0·8347	160·7	−0·3
21[25]	1965	0·8376	160·9	−0·8

Note: $\Delta\hat{\lambda}°$ is the difference between $\hat{\lambda}$ and the best straight line relationship between $\hat{\lambda}$ and T (see equation (6)).

Drift of the Geomagnetic Field

The first spherical harmonic analysis of the geomagnetic field was done by Gauss for epoch 1835 (see Table 5). This and subsequent analyses revealed details of slow secular changes in **B**, including the westward drift of the field pattern first noted by Halley in the seventeenth century.

Comparable gravitational data are not available, but it is reasonable to suppose that **g** remains fixed on this time scale. Distortions in **g** at the Earth's surface must be due to density variations in the solid part of the Earth, concomitant stresses being roughly 10^8 N m^{-2}. Stresses of this magnitude could be supported[5] elastically or by viscous forces (associated with very slow motions, on geological time scales) in the mantle and crust, but they are too large, by several orders of magnitude, to be associated with processes in the core, where the geomagnetic field originates.

Values of $\hat{k}$ and $\hat{\lambda}$ when $r=R$ and $n^*=4$ evaluated for different epochs going back to 1835 are given in Table 5, and the corresponding variations of $\hat{k}$ and $\hat{\lambda}$ with time T are illustrated in Figs. 2 and 3. The tendency for $\hat{k}$ to increase with T prior to 1920 before flattening out at a value somewhat greater than 0·8 is presumably due largely to the general improvement in the accuracy and coverage of the basic magnetic data. The tendency for $\hat{\lambda}$ to increase with time T is a manifestation of the westward drift. The data of Table 5 and Fig. 3 fit the straight line

$$\hat{\lambda}=(126\cdot2\pm0\cdot2)°+(0\cdot273\pm0\cdot005)[T\pm10-1835]° \quad \text{(standard errors)} \quad (6)$$

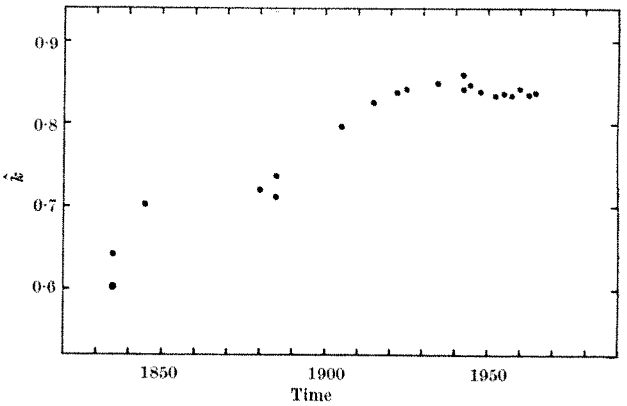

Fig. 2. The variation of $\hat{k}$ with time when $n^*=4$ (see Table 5).

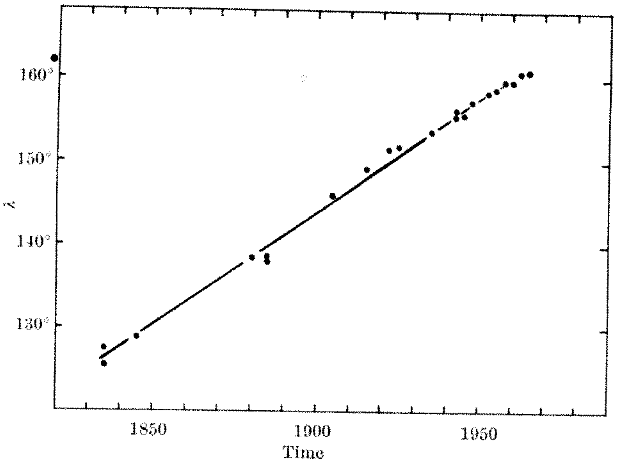

Fig. 3. The variation of $\hat{\lambda}$ with time when $n^* = 4$ (see Table 5 and equation (6)).

very closely indeed, where T is the epoch in year AD.

If the correlation between **B** and **ĝ** is a manifestation of strong magnetohydrodynamic interactions between core motions and bumps on the core–mantle interface[2,3], then the main features of the drifting part of the non-dipole component of the present geomagnetic field might have been produced by such an interaction about 500 years ago, when (if we assume that equation (6) was at least roughly applicable at and since that time) $\hat{\lambda}$ was still positive but very small. This tentative conclusion is consistent both with theoretical ideas concerning the rates of propagation and dispersion of free magnetohydrodynamic oscillations of the core[2] and with archaeomagnetic data[28], which indicate that 0·23 ± 0·06 degrees of longitude per year has been the westward drift rate since about 1400 but that the drift was much slower and possibly even eastward between 1100 and 1400.

Received November 24, 1969; revised January 22, 1970.

Appendices

(A) The infinite series introduced in equation (1) is defined as follows

$$\sum_{n=1}^{\infty}\sum_{m=0}^{n} S(A_n, A_n^m, B_n^m) \equiv \sum_{n=1}^{\infty} A_n\left(\frac{R}{r}\right)^{n+1} P_n(\cos\varphi) + \sum_{n=1}^{\infty}\sum_{m=1}^{n}\left(\frac{R}{r}\right)^{n+1} P_n^m(\cos\varphi)[A_n^m \cos m\lambda + B_n^m \sin m\lambda] \qquad \text{(A1)}$$

where

$$P_n(x) \equiv \frac{1}{2^n n!}\,\frac{\mathrm{d}^n}{\mathrm{d}x^n}\,(x^2-1)^n \qquad \text{(A2)}$$

and

$$P_n^m(x) \equiv \left[\frac{2(2n+1)(n-m)!}{(n+m)!}\right]^{1/2}(1-x^2)^{m/2}\,\frac{\mathrm{d}^m}{\mathrm{d}x^m}\,P_n(x) \qquad \text{(A3)}$$

The terms involving the dimensionless coefficients A_n are the zonal harmonics, which are independent of λ, and those involving the pairs of coefficients (A_n^m, B_n^m) are the tesseral harmonics[6,7].

The dimensionless coefficients (a_n^m, b_n^m) appearing in equation (2) are related as follows to the Schmidt quasi-normal coefficients[8,9] generally used in geomagnetic work

$$(a_n^m, b_n^m) = [R^3/a_1 L(2n+1)^{1/2}](g_n^m, h_n^m) \qquad \text{(A4)}$$

(B) The coefficient of correlation between U and V at $r = R$ is given by the equation

$$k = \frac{\sum_{m,n}(a_n^m A_n^m + b_n^m B_n^m)}{[\sum_{m,n}[(a_n^m)^2+(b_n^m)^2]]^{1/2}[\sum_{m,n}[(A_n^m)^2+(B_n^m)^2]]^{1/2}} \qquad \text{(B1)}$$

with corresponding expressions involving $(\dot{a}_n^m, \dot{b}_n^m)$ and (α_n^m, β_n^m) for the drifting and non-drifting secular variation fields (see equation (3) and compare equation (6)).

(C) Introduce the following quantities:

$$c_n^m \equiv [(a_n^m)^2+(b_n^m)^2]^{1/2},\quad \theta_n^m \equiv \tan^{-1}(b_n^m/a_n^m) \qquad \text{(C1)}$$

$$C_n^m \equiv [(A_n^m)^2+(B_n^m)^2]^{1/2},\quad \Theta_n^m \equiv \tan^{-1}(B_n^m/A_n^m) \qquad \text{(C2)}$$

$$\hat{\theta}_n^m \equiv \theta_n^m - m\hat{\lambda} \qquad \text{(C3)}$$

$$\delta_n^m \equiv \hat{\theta}_n^m - \Theta_n^m \qquad \text{(C4)}$$

and

$$Q_{m,n} \equiv |\delta_n^m|/\pi \qquad \text{(C5)}$$

Brier's test is based on the fact that if the angles δ_n^m are distributed uniformly and independently of each other over the interval $-\pi$ to π, then the coefficients $Q_{m,n}$ should average 0·5.

The weighted standard deviate y is given by[27]

$$y = \frac{\sum_{m,n}(c_n^m C_n^m Q_{m,n}) - \frac{1}{2}\sum_{m,n}(c_n^m C_n^m)}{[\sum_{m,n}(c_n^m C_n^m)^2/12]^{1/2}} \qquad \text{(C6)}$$

On the null hypothesis that (a_n^m, b_n^m) and (A_n^m, B_n^m) are not correlated, the most probable value of y from a large sample would be zero. The probability p that the data are uncorrelated may be related to y via q, the proportion of the total area under the normal error curve lying to the left of $|y|$, which can be found from tables[26].

$$q = 1 - \tfrac{1}{2}p \qquad \text{(C7)}$$

Brier's test is much more stringent than the Student t test and seems to take into account all the factors in the particular problem in hand that renders the t test inadequate.

Abundance of Iron in the Solar Photosphere

by
JOHN E. ROSS
Department of Astronomy,
University of California,
Los Angeles

Recent measurements of iron *f*-values indicate that the iron abundance derived from neutral iron lines formed in the solar photosphere based on older *f*-values should be increased by a factor of ~ 5. This increase is partially offset if the damping constant is taken into account.

THE solar iron abundance has been intensively investigated because photospheric determinations seem to give a substantially smaller iron/silicon ratio than do the coronal. The ratio found by Pottasch[1] agrees with an average ratio for the chondritic meteorites, and some writers argue that the photospheric result is spurious.

Recent measurements of iron *f*-values (unpublished work of S. J. Wolnik *et al.* and ref. 2) indicate systematic errors in *f*-values of transitions arising from high upper levels ($\chi_u > 3$ eV) in earlier *f*-value compilations[3,4]. A straightforward application of these new *f*-values by Garz *et al.*[5] in a curve of growth analysis yields a solar iron abundance $\log [N(\mathrm{Fe})/N(\mathrm{H})] + 12 = \{\mathrm{Fe}\} = 7{\cdot}5$, a value in agreement with the coronal and meteoric determinations.

These authors have used the total intensities (equivalent widths, W_λ) of the lines, ignoring the information contained in the shape or profile of the line. It is the purpose of this article to emphasize the importance of the line profile in abundance analysis.

The Emergent Line Profile

From the most elementary point of view, the emergent (observable) profile of a spectrum line is governed intrinsically by the mean profile of the line absorption coefficient, and extrinsically by large-scale photospheric motions.

The photospheric absorption coefficient of a neutral iron line is broadened simultaneously by collisions with neutral hydrogen atoms (the width at half-intensity characterized by Γ_v), by thermal doppler effects, and by small-scale photospheric motions commonly called microturbulence. By contrast, large-scale (that is, no relative motion within the region of line formation) photospheric motions involved in extrinsic broadening are called "macroturbulence". The most probable microturbulent and macroturbulent velocities are denoted by ξ and Ξ respectively.

If the physical state of the solar atmosphere in the region of line formation is known, the uncertain quantities governing the theoretical line profiles are the kinematical parameters ξ and Ξ, the atomic parameters, Γ_v, and the product of the abundance $N(\mathrm{Fe})$ and the Ladenburg f, $N(\mathrm{Fe})f$. Inadequacy in theory and observations prevents the extraction of these parameters from a single line; instead, one must obtain ξ and Ξ from judiciously chosen lines and then deduce Nf and Γ_v for each line, subject to uncertainties in ξ and Ξ. We now consider each of these effects in turn.

Macroturbulence in the solar photosphere has little effect on the equivalent width of the line. Significantly, the effect on the line profile is to mimic both ξ and Γ_v, thus rendering any empirical evaluation of the latter parameters by profile analysis extremely difficult. To some extent, a determination of Ξ seems straightforward. If we take $\xi = 2$ km s^{-1} and increase Γ_v to ten times its theoretical value, $\Xi \sim 1{\cdot}8$ km s^{-1} is required to bring theoretically computed, crowded spectral regions into accord with observations. If we take $\xi = 0$ and $\Gamma_v = 0$ we obtain an upper limit $\Xi \sim 2{\cdot}5$ km s^{-1}. Preliminary studies indicate $\xi^2 + \Xi^2 \sim 5$ km s^{-1} with the most probable values being $\Xi = 2{\cdot}2$ km s^{-1} and $\xi = 1$ km s^{-1}, which are adopted for this analysis. The instrumental profile inserts a smearing effect similar to macroturbulence. The effective smearing corresponds to a doppler velocity < 1 km s^{-1} which would make the true macroturbulent velocity ~ 2 km s^{-1}.

Microturbulence in the photosphere gives rise to a doppler effect analogous to the thermal doppler broadening of the line absorption coefficient. The appropriate value of ξ as a function of optical depth in the photosphere has not been satisfactorily determined, and the depth independent value $\xi = 1$ km s^{-1} has been arbitrarily adopted. The equivalent widths of medium-strength lines are strongly dependent on ξ; in any instance where ξ affects the results of the analysis, the quantity $\mathrm{d}[\log (N)]/\mathrm{d}\xi$ is given, enabling the results to be adjusted within the range $0{\cdot}5 < \xi < 1{\cdot}5$ km s^{-1}.

The damping constant affects the equivalent widths of medium-strength to strong (saturated) lines. In the limiting case of strong lines, the line strength and profile are determined by the product $Nf\Gamma_v$, and separation of Nf and Γ_v becomes impossible. In the limiting case of weak lines, Nf determines the line strength, and ξ, Ξ and Γ_v determine the line profile. The value of Γ_v in the case of weak lines is determinable only if the damping half-width is comparable with the combined ξ, Ξ half-width. In the case of medium-strength lines, Γ_v is determinable by profile analysis within limits imposed by observations and uncertainties in Ξ; the larger the damping constant, the more precise the determination.

The chief contribution to the damping constant of a neutral iron line in the solar photosphere arises from collisions with neutral hydrogen atoms. The impact approximation as proposed by Unsold[6] or used by Aller[7], for example (utilizing Coulomb wave functions, or scaled Thomas–Fermi (STF) wave functions[8]), is invariably used to evaluate Γ_v. In the case of neutral iron the approximation is questionable and there is evidence which indicates that the theory predicts damping constants that are too low by factors ranging from two to ten for $\chi_u < 6$ eV.

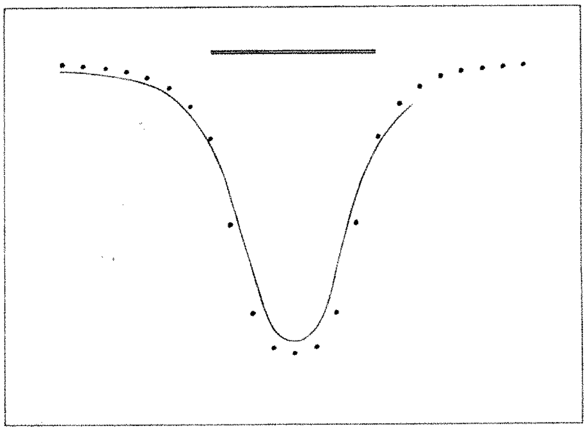

Fig. 1. Fe I $\lambda 5{,}434{\cdot}5$ a^5F–$z^5D°$ transition. The solid line represents both the observed profile and a synthetic profile for $\{\mathrm{Fe}\} = 6{\cdot}7$, $\Gamma_v = 12\Gamma_v^{\mathrm{stf}}$. The dotted line is a synthetic profile with $\{\mathrm{Fe}\} = 7{\cdot}7$ and $\Gamma_v = \Gamma_v^{\mathrm{stf}}$. The residual intensity in the observed line core is 0·15 that of the continuum (double horizontal bar).

Kusch[9] has determined Γ_v experimentally for a number of neutral iron lines. If the ratio $\Gamma^0_v = \Gamma_v$ (Kusch)/$\Gamma_v{}^{\mathrm{stf}}$ versus χ_u is plotted, a fit to the lower envelope of the points gives

$$\Gamma_v \sim 30{\cdot}7 - 11{\cdot}5\ \chi_u + 1{\cdot}524\ \chi_u{}^2 - 0{\cdot}07111\ \chi_u{}^3\ (3 < \chi_u < 5{\cdot}5\ \mathrm{eV})$$

for s–p transitions (that is, transitions arising from even-parity lower levels). The damping constants for p–s transitions with $\chi_u \sim 5{\cdot}5$ eV scatter around $2 < \Gamma^0_v < 8$.

Wolnik *et al.*[10] present an empirical curve of growth obtained from shock-tube measurements of neutral chromium. The damping to doppler ratio indicated by the curve of growth suggests damping in excess of that predicted by theory. Because Cr and Fe are similar in atomic structure, one would expect that a similar excess occurs in iron.

Abundance Determination

The photospheric abundance determination has been attacked from several points of view by a combination of the direct–profile–integration curve of growth method[11], and by spectrum line synthesis[12]. Equivalent widths were taken from the second revision of Rowland's table[13]. Line profiles were obtained at the McMath–Hulbert Observatory. Corliss and Tech[4] *f*-values are denoted by "CT", *f*-values from unpublished work of Wolnik *et al.* by "W" and Garz and Kock[2] *f*-values by "GK". Unless otherwise specified, two values of the damping constant were used: theoretical[8] ($\Gamma_v{}^{\mathrm{stf}}$), and half the value given by the fit to Kusch's[9] lower envelope fit ($\Gamma_v{}^{\mathrm{K}}$).

The photospheric model is due to Elste[14], but the results are insensitive to the model employed.

(i) A curve of growth analysis of fifty weak ($W_\lambda < 0{\cdot}03$ Å) high excitation lines in the wavelength region $5000 < \lambda < 6000$ Å gives $\{\mathrm{Fe}\} = \log\ [N(\mathrm{Fe})/N(\mathrm{H})] + 12 = 6{\cdot}4 \pm 0{\cdot}2$ based on CT *f*-values. Adopting the correction indicated by Wolnik *et al.*, $\Delta gf = \log\ [gf(\mathrm{CT})/gf(\mathrm{W})] \lesssim 0{\cdot}7$, these lines give $\{\mathrm{Fe}\} \lesssim 7{\cdot}1$. Dependence on Γ_v and ξ is negligible for these lines.

(ii) A curve of growth analysis of thirty-five low excitation lines belonging to multiplets 1, 12, 13, 15 and 16 gives $\{\mathrm{Fe}\} \sim 6{\cdot}8$ for the weaker lines and $\{\mathrm{Fe}\} \sim 7{\cdot}5$ for the stronger lines using CT *f*-values and Γ^{stf}. If $\Gamma_v{}^{\mathrm{K}}$ is employed, $\{\mathrm{Fe}\} \sim 6{\cdot}9 \pm 0{\cdot}2$, with a marked reduction in the scatter of abundances about the mean value. $\Delta gf \sim 0{\cdot}2$ for these multiplets (with the exception of multiplet 15) (ref. 15) resulting in $\{\mathrm{Fe}\} \sim 7{\cdot}1$ with $\mathrm{d}\{\mathrm{Fe}\}/\mathrm{d}\xi = 0{\cdot}3$.

(iii) A curve of growth analysis of twenty-six s–p and forty-four p–s lines, for which W *f*-values are available, gives $\{\mathrm{Fe}\} \sim 7{\cdot}4 \pm 0{\cdot}25$, $\mathrm{d}\{\mathrm{Fe}\}/\mathrm{d}\xi = 0{\cdot}3$, a value in accord with the analysis of Garz *et al.*[5] whose results were reproduced as a procedural check. If $\Gamma_v{}^{\mathrm{K}}$ is adopted, the s–p transitions give $\{\mathrm{Fe}\} = 7{\cdot}15 \pm 0{\cdot}2$, $\mathrm{d}\{\mathrm{Fe}\}/\mathrm{d}\xi\ 0{\cdot}2$. If $\Gamma^0_v = 4$, as Kusch indicates for p–s transitions, the p–s lines give $\{\mathrm{Fe}\} = 7{\cdot}15 \pm 0{\cdot}2$, $\mathrm{d}\{\mathrm{Fe}\}/\mathrm{d}\xi = 0{\cdot}25$.

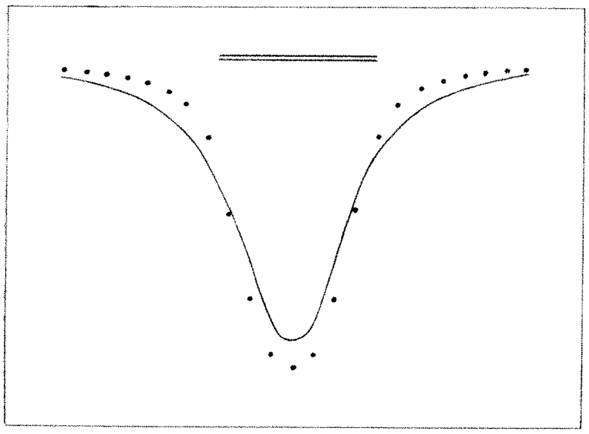

Fig. 2. Fe I λ5,568·6 z^5F°–e^5D transition. The solid line represents both the observed profile and a synthetic profile for $\{\mathrm{Fe}\} = 6{\cdot}85$, $\Gamma_v = 12L_v{}^{\mathrm{stf}}$. The dotted line is a synthetic profile for $\{\mathrm{Fe}\} = 7{\cdot}7$ and $\Gamma_v = \Gamma_v{}^{\mathrm{stf}}$. The intensity in the observed line core is 0·18 that of the continuum (double horizontal bar).

(iv) The synthesis method was applied to five of the least blended s–p lines having W and GK *f*-values. The damping constant is intrinsically small[8] for these lines and separation of $N(\mathrm{Fe})$ from Γ is difficult, but the use of $\Gamma_v{}^{\mathrm{K}}$ gives systematically better profile fits (see Fig. 1).

(v) The synthesis method was applied to ten of the least blended p–s lines having W and GK *f*-values. These lines naturally have theoretical damping constants which are an order of magnitude greater than the s–p lines studied[8]. The damping constants for medium-strength p–s lines are easily separable from $N(\mathrm{Fe})$ and there is little doubt that these transitions have damping constants several times that predicted by theory (see Fig. 2).

(vi) The appropriate damping constants for multiplets 15, 16, 553 and 1,146 were derived by a (non-linear) least-squares analysis. Assuming the damping constant to be the same for all members of a given multiplet, the minimum abundance scatter occurs with $\Gamma_v > \Gamma_v{}^{\mathrm{stf}}$ for multiplets 15, 553 and 1,146 (W *f*-values) and $\Gamma_v = 6\Gamma_v{}^{\mathrm{stf}}$ for multiplet 16 (CT *f*-values).

Discussion

A straightforward curve-of-growth analysis using γ-values from Wolnick *et al.* or from Garz and Kock[2] and theoretical (STF) damping constants yield

$$\{\mathrm{Fe}\} = 7{\cdot}4 \pm 0{\cdot}3,\quad \mathrm{d}\{\mathrm{Fe}\}/\mathrm{d}\xi = -0{\cdot}3$$

A profile analysis indicates Γ_v should be increased over the theoretical value for s–p transitions, and shows conclusively that Γ_v must be increased for p–s transitions. If Γ_v is increased four times for p–s transitions, and half the damping given by the fit to Kusch's[9] data is employed for s–p transitions, then $\{\mathrm{Fe}\} = 7{\cdot}15 \pm 0{\cdot}2$, $\mathrm{d}\{\mathrm{Fe}\}/\mathrm{d}\xi = -0{\cdot}25$, and the computed profiles are in better agreement with observations. If the damping is indeed as large as that indicated by Kusch, a value which would not conflict with profile analysis, $\{\mathrm{Fe}\} \lesssim 6{\cdot}9$ is indicated.

The photospheric iron abundance must be considered uncertain until reliable damping constants are obtained for lines having reliable *f*-values, or until reliable *f*-values for weak lines are found. This analysis indicates, however, that $\{\mathrm{Fe}\} = 7{\cdot}2$ should be considered an upper bound based on the newer *f*-values (unpublished work of Wolnick *et al.* and ref. 2).

I thank Professor L. H. Aller for guidance in the abundance problem, Dr Gordon Wares for *f*-values in advance of publication, and Dr Orren Mohler and Dr Walter S. Mitchell for observational data in advance of publication. Part of the computing costs and use of the computing facilities were provided by Campus Computing Network, University of California, Los Angeles. The programme is supported by a NASA grant to the University of California, Los Angeles.

Possible Mechanism for the Pulsar Radio Emission

by
M. M. KOMESAROFF
Division of Radiophysics,
CSIRO, Sydney,
Australia

An attempt to account quantitatively for the pulse width, polarization and spectrum of the pulses.

ANY explanation of the pulsar radio emission must take account of the fact that although a pulsar may emit highly variable individual pulses, the average properties of a large number observed at a fixed wavelength are characteristic of that particular pulsar and show the following features (some of which come from the unpublished work of myself and my colleagues). (*a*) The pulse duration is a small fraction of the interval between pulses. (*b*) The pulse energy is extremely intense and usually varies approximately at the wavelength (λ) for values of λ down to about 0·2 m. For shorter wavelengths the spectral decrease may be much steeper[1]. (*c*) The average pulse is usually single or double, although higher order multiplicities are sometimes observed. (*d*) The pulse shape is a slowly varying function of wavelength. (*e*) For pulsars which emit pulses with double structure (such as NP 0527, CP 1133 and PSR 2045–16), the spacing between components varies[2,3] approximately as $\lambda^{1/4}$. Drake has indicated that at very long wavelengths the intrinsic pulse shapes of several pulsars become double (Sixteenth General Assembly of URSI, Ottawa, 1969). (*f*) In several cases the pulse is almost completely linearly polarized. Examples are PSR 0833–45 and PSR 1929+10 (ref. 4). (*g*) For PSR 0833–45, the plane of polarization rotates through a large angle during the pulse, and the rate of rotation is almost independent of wavelength[5,6]. (*h*) In the case of the double pulses emitted by MP 0736 and PSR 2045–16 a very rapid change in the direction of polarization is observed near the time of bifurcation of the pulse.

In explanation of the PSR 0833–45 results (*f*) and (*g*), Radhakrishnan and Cooke[5] have suggested that the radiation is sharply beamed from the vicinity of a magnetic pole, and that the position angle reflects the instantaneous direction of the magnetic field lines in the emitting region. More recently Radhakrishnan[7] has proposed that the radiation is produced by relativistic particles moving almost directly along the magnetic field lines and radiating by virtue of the acceleration associated with the curvature of these lines, in contrast with the synchrotron radiation produced by particles gyrating around the field lines.

The present argument carries Radhakrishnan's suggestions a step further and attempts to account quantitatively for the pulse width, polarization and spectrum of the pulses.

Assumptions for the Pulsar Model

Almost any attempt to explain the intensity of the pulsar radio emission must have recourse to the concept of coherence, that is, of large numbers of particles emitting "in phase". In view of the spectrum this implies correlated fluctuations of particle density extending over only a few centimetres along the line of sight. To account for the intensity of the radiation without invoking prohibitively large densities of particles, we must assume that in the direction perpendicular to the line of sight the correlated fluctuations extend over some hundreds of metres. I therefore suggest the following model of a pulsar:

(i) Pulsars are rotating neutron stars (radius $\approx 10^4$ m) with surface magnetic fields as large as 10^{12} G. The magnetic field near the stellar surface is assumed to be approximately dipolar.

(ii) The magnetic axes make large angles (≈ 1 rad) with the rotational axes[8].

(iii) The radiation is produced by short-duration fluctuations of charged particle density extending over only a fraction of a metre in the direction of the field lines, and extending over a few hundred metres in the direction perpendicular to the field lines.

(iv) The particles are accelerated to relativistic velocities within a very short distance of the stellar surface, and those responsible for the radio emission move almost directly along the magnetic field lines with negligible velocity of gyration.

(v) The relevant particles are predominantly those moving along particular groups of field lines having radii of curvature of the same order as those lines which would be tangential to the velocity-of-light cylinder if the dipole configuration were maintained out to that distance.

(vi) The fluctuating component of particle density, N, falls off less rapidly than does the magnetic field. I assume that N is approximately proportional to $B^{1/2}$, which implies that the fluctuations are enhanced as they move outward.

Assumptions (v) and (vi) will be discussed in more detail later. They imply that most of the radio emission originates within a few radii of the stellar surface and well within the velocity-of-light cylinder.

Radiation from the Model Pulsar

A charged particle moving along a curved field line emits a "spike" of energy toward a distant observer from that point at which the tangent to the field line is most nearly parallel to the observer's line of sight. The radiation is beamed into a small angle along the tangent, mainly at frequencies below a "critical frequency" f_c, given by[9]

$$f_c = \frac{3\gamma^3 c}{\pi \rho} \tag{1}$$

where ρ is the radius of curvature of the line and γ is the ratio of the total energy to the rest energy of the particle. Within a few degrees of a magnetic pole

$$\rho = \frac{4r}{3\theta} \tag{2}$$

where r and θ are polar coordinates measured with respect to the magnetic axis. Combining equations (1) and (2),

$$f_c = \frac{9\gamma^3 c\theta}{16\pi r}$$

For $\gamma \gtrsim 10^3$, $\theta \gtrsim 1/30$ rad, and $r \lesssim 3 \times 10^4$ m, $f_c \gtrsim 10^{11}$ Hz, and so most of the emission would be in the radio domain.

The E-vector of the radiation received at any instant will be approximately in the plane of the field line pointing toward the observer. Because this plane necessarily contains the magnetic axis, the position angle (P.A.) of the E-vector will be nearly the same as the position angle of the magnetic axis. Measured with respect to the rotational axis

$$\tan(\text{P.A.}) = \frac{\sin\chi \sin l}{\sin\varphi \cos\chi - \cos\varphi \sin\chi \cos l} \tag{3}$$

$$\left. \mathrm{d}(\text{P.A.})/\mathrm{d}l \right|_{l=0} = \frac{\sin\chi}{\sin(\varphi - \chi)}$$

where χ and φ are the angles made by the magnetic axis and the line of sight respectively with the rotational axis; l is the longitude of the magnetic axis with respect to the plane containing the rotational axis and the observer.

From equation (3) it follows that if the line of sight lies exactly on the cone swept out by the magnetic axis ($\chi = \varphi$), the position angle changes discontinuously from $-\pi/2$ to $+\pi/2$ as l passes through zero. In this situation a double pulse will be observed. If the line of sight only grazes the beam of emission, a single pulse will be observed. As shown below, the total emission beam has a narrow angular radius, and because according to assumption (ii), $\sin\chi \approx 1$, $\mathrm{d(P.A.)}/\mathrm{d}l \gg 1$.

For frequencies well below the critical frequency, in the plane "tangential" to the field line (see Fig. 1), the emission from a single particle is confined chiefly to an angle of about $2\xi_c$, where

$$\xi_c = \left(\frac{3\lambda}{2\pi\rho}\right)^{1/3} \tag{4}$$

Taking into account equation (2) and the equation of a field line, which is

$$r = r_e \sin^2\theta = r_e\theta^2, \text{ for small } \theta \tag{5}$$

(see Fig. 2), then

$$\xi_c = \left(\frac{9\lambda}{8\pi r_e\theta}\right)^{1/3} \tag{6}$$

The energy density emitted by the particle[9] is approximately

$$\frac{\mathrm{d}I(f)}{\mathrm{d}\Omega} = K\xi_c^{-2} \text{ J sr}^{-1} \text{ Hz}^{-1}$$

where $K = 1{\cdot}2 \times 10^{-36}$ if the particle carries one electronic charge, and Ω represents solid angle.

The radius of curvature of the surface perpendicular to the field lines in the polar region is

$$\rho_V = (2{\cdot}3)r = (2/3)r_e\theta^2$$

and the angular radius of the first Fresnel zone associated with this surface can be seen from Fig. 1 to be

$$\xi_F = \left(\frac{\lambda}{\rho_V}\right)^{1/2} = \left(\frac{3}{2}\frac{\lambda}{r_e}\right)^{1/2}\theta^{-1} \tag{7}$$

In general, for small values of θ, $\xi_c \ll \xi_F$ at the stellar surface, but as θ increases ξ_F decreases more rapidly than ξ_c. For $\xi_c < \xi_F$, the volume containing all those particles which emit in-phase is

$$V = \pi\rho_V^2\,\xi_c\,\xi_F\,d$$

d being the "thickness" of the bunch. By virtue of the in-phase emission the total energy density is proportional to the square of the number of emitting particles and is given by

$$J = N^2(\theta)\,V^2\frac{\mathrm{d}I(f)}{\mathrm{d}\Omega} = \pi^2 K N^2(\theta)\,d^2 \cdot \rho_V^3 \cdot \lambda$$

According to assumption (vi), the particle density along a particular field line may be written $N(\theta) = N_0\theta^{-3}$, where N_0 is the particle density at the stellar surface. Thus substituting for ρ_V

$$J = \pi^2 K N_0^2 (2/3\,r_e)^3\,\lambda d^2 \tag{8}$$

This will hold provided $\lambda > d$, and hence yields the approximate spectral law mentioned in (*b*).

Equation (8) only applies if $\xi_c < \xi_F$. For larger values of θ, $\xi_c > \xi_F$, and in-phase radiation is emitted only from the volume $\pi\rho_V^2\,\xi_F^2$, because contributions from outside the first Fresnel zone will be in antiphase with the main emission (Fig. 1). For this region the value of J given by equation (8) must be multiplied by ξ_F^2/ξ_c^2, which varies as $\theta^{-4/3}$, and therefore $\xi_c = \xi_F$ defines the region of strong emission. We define θ_m to be that angle for which $\xi_c = \xi_F$. From equations (6) and (7)

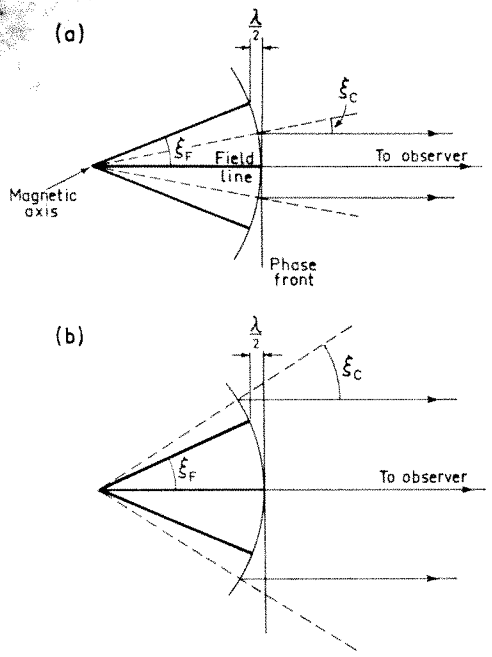

Fig. 1. The plane of this figure (the "tangent plane") contains the tangent to a field line and is perpendicular to the plane of the line. The field lines as projected on this plane are shown as radii of the circular arc, which is a section of the surface normal to the lines. Two cases are shown: (*a*) $\xi_c < \xi_F$. All the radiation reaching the observer is emitted within the first Fresnel zone and is therefore in-phase. (*b*) $\xi_c > \xi_F$. Some of the radiation is emitted from beyond the first Fresnel zone and is therefore in antiphase with the main emission. (Sizes of angles have been exaggerated for the sake of clarity.)

$$\theta_m = 2{\cdot}26\left(\frac{\lambda}{r_e}\right)^{1/4} \text{ rad}$$

The tangent to the field line at the point (r, θ_m) makes an angle $\psi = 3/3\,\theta_m$ with the magnetic axis (see Fig. 2). Thus the spacing between emission maxima is

$$2\psi = 3\theta_m = 6{\cdot}8\left(\frac{\lambda}{r_e}\right)^{1/4} \text{ rad} \tag{9}$$

The form of this wavelength dependence is that required by (*e*) above.

Assuming that the field lines involved are those approximately tangential to the velocity-of-light cylinder, then

$$r_e = \frac{cP}{2\pi}$$

(Fig. 2), where P is the rotation period in seconds and

$$2\psi = 8 \times 10^{-2}\left(\frac{\lambda}{P}\right)^{1/4} \text{ rad} \tag{10}$$

Because the dependence on P is so slow, it could be masked by variations of geometry from pulsar to pulsar.

Finally, it should be noted that for typical values of P and λ most of the radiation is emitted within a few stellar radii of the neutron star, well within the velocity-of-light cylinder.

Discussion

According to the model just outlined, pulsar radiation is emitted in a hollow beam coaxial with the magnetic axis, and the pulses are produced by the motion of this beam past the line of sight as a result of rotation. The pulses are single or double depending on whether the beam merely grazes the line of sight or intersects it twice. The model provides an explanation for the observed variation of polarization position angle within the pulse, and also

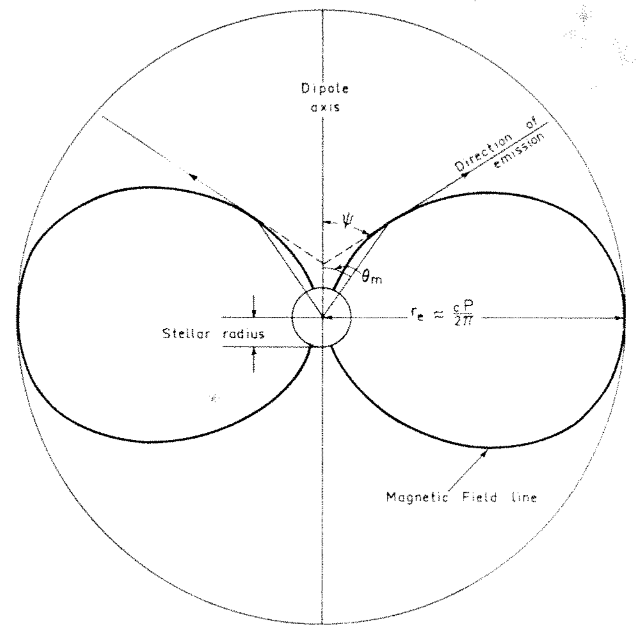

Fig. 2. The plane containing the magnetic axis, assumed to be at a large angle to the rotational axis. The larger circle represents a section of the velocity-of-light cylinder. The diagram is not drawn to scale (the radius of the light cylinder is actually hundreds or thousands of times greater than that of the star, and the angles θ_m and ψ are shown very much enlarged).

accounts for the wavelength dependence of the component spacing in double pulses. If we let $\lambda = 1$ m and $P = 1$ s, we find from equation (10) that $2\psi = 4°{\cdot}6$, which is of the right order but smaller by a factor of about 1·5 than the value actually observed for CP 1133 ($P = 1{\cdot}18$ s). The discrepancy is in the same sense but greater in the case of NP 0527, MP 0736 and PSR 2045–16. This could indicate that we were mistaken in assuming that the angle between the magnetic and rotational axes is necessarily "large" (that is, ≈ 1 rad); alternatively the explanation may be in terms of departures from a dipole configuration.

The form of the spectrum given by equation (8) is in rough agreement with observation down to $\lambda \approx 0{\cdot}2$ m. If we assume that d is of this order, the break in the spectrum of many pulsars can be explained.

Equation (8) permits an estimate of the required value of N_0, the fluctuating component of particle density at the stellar surface. Large *et al.*[10,11] find that for many pulsars the energy density per pulse at $\lambda = 0{\cdot}75$ m is about 10^{-27} J m^{-2} Hz^{-1}. Assuming that each pulse represents the radiation from a hundred or more fluctuations and that the average distance of a pulsar from the Earth is about 0·5 kpc ($1{\cdot}5 \times 10^{19}$ m), we find that $N_0 \leq 10^{10}$ cm^{-3}. Goldreich and Julian[12], considering the case of an axisymmetric neutron star, find that the space charge density is $7 \times 10^{-2}\ B_z/P$, where B_z is the component of magnetic field parallel to the rotation axis. For $P = 1$ s and $B_z \approx 10^{12}$ G, the space charge density in the co-rotating domain is 10^{11} electronic charges per cm^3.

The assumption of correlated density fluctuations has been introduced without physical justification. Some such assumption seems almost essential on any theory, in order to account for the enormously intense radio emission, without invoking prohibitively large numbers of radiating particles. The fact that, according to the present model, the fluctuations move along those field lines approximately tangential to the light cylinder suggests that they may be established as a result of disturbances propagated inward along these lines due to the kind of effect discussed by Gold[13].

Because the polarized optical emission observed in the case of NP 0532 (refs. 14–16) is presumably synchrotron radiation due to particle gyration around the field lines, it would have its E-vector approximately perpendicular to that of the radiation produced by the mechanism described earlier. Observations of the radio polarization from this pulsar could provide a critical test of the present model.

I thank several of the staff of the Division of Radiophysics for helpful criticism.

Observations of Atmospheric Turbulence with a Radio Telescope at 5 GHz

by
R. A. HINDER
Mullard Radio Astronomy Observatory,
Cavendish Laboratory,
University of Cambridge

Variations of the radio refractive index of the atmosphere are important to radio astronomers and in satellite communications. This article describes the situation at 5 GHz, based on work with the one-mile telescope at Cambridge.

CHANGES of pressure, temperature and humidity cause variations of the radio refractive index of the troposphere. Such variations are naturally of interest to meteorologists, but have recently become of practical importance in setting a limit to the resolving power of radio telescopes. They may also affect the performance of satellite communications systems. The next generation of radio telescopes using the technique of aperture synthesis may well achieve the maximum resolution which is attainable in the presence of the variations. In this context it is important to know how the electrical path length from an extraterrestrial radio source to the ground is influenced by the refractive index variations occurring along lines of sight through the atmosphere, and in particular how the resulting changes in path length are correlated on adjacent lines of sight.

Some investigators are studying refractive index variations with airborne refractometers[1], but their results apply only to local changes. An alternative technique, using a radio interferometer, measures the effect on path length directly. In this method (Fig. 1), waves from a radio source pass through the atmosphere to two aerials A_1 and A_2 spaced laterally on the ground. A line P_1P_2 above the atmosphere is drawn parallel with the line joining the two aerials so that P_1A_1 and P_2A_2 are the ends of ray paths from the radio source to the telescope. Knowing the position of the source, the relative phase of the signals at P_1 and P_2 can be continuously computed so that departures of the measured phase differences between signals at A_1 and A_2 from the computed values allow variations in the integrated phase path through the atmosphere to be found.

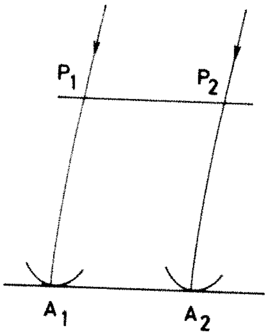

Fig. 1. Radio paths through the atmosphere from a point source to an interferometer.

For very small separations the ray paths are nearly coincident and the phase departures are common to both so that the observed phase differences show little fluctuation due to the atmosphere. As the aerials are separated the correlation between the phase fluctuations along the two paths becomes smaller, and the observed phase differences increase. The variance of the phase difference for a given separation therefore depends on the autocovariance of fluctuations in the refractive index. Because the refractive index of air is non-dispersive at radio wavelengths, the phase differences are proportional to the observing frequency.

This method has been used by Baars[2] and Basart *et al.* (unpublished) at the US National Radio Astronomy Observatory using a frequency of 2·7 GHz and baselines up to 35 km, and more recently by Gent *et al.*[3] with the RRE interferometer, also at 2·7 GHz. Their observations have demonstrated the existence of the phase variations, and suggest that they may be associated with meteorological phenomena. But no detailed evidence on the scale of the variations and how they are related to the time of day or season has yet been put forward.

This article describes the results of a more extensive series of observations carried out since 1967 at Cambridge with the one-mile radio telescope operating at 5 GHz, in order to investigate the incidence and nature of refractive index fluctuations over the UK. For these observations the three aerials comprising the telescope provide three overlapping baselines having different separations.

It has been found that the phase variations originate in a pattern of refractive index variations which moves across the telescope at wind speeds and does not as a rule evolve and decay in the time taken to move across the telescope. The observed time variations can therefore be related to spatial variations of the refractive index of the air. In this way observations made at many different aerial separations from 0·05 to 1·6 km have allowed a direct measurement of structure in this range of scale sizes; furthermore, as the pattern is effectively frozen, useful information on larger scale sizes up to about 10 km has been obtained by looking at time variations which last longer than the time taken for a feature to move across the telescope. The observations have also shown that both the scale size and the magnitude of the irregularities vary from day to day and from season to season.

Observations

A detailed description of the one-mile telescope has already been published[4]. The phases of signals received at each of three aerials are compared every 20 s and the differences between these values are related in a computer to the values expected in the absence of atmospheric refraction. The phase departures are automatically presented on a curve plotter attached to the computer, and results for typical runs are shown in Fig. 2. Three such curves are derived simultaneously, one for each pair of aerials in the telescope. Most of the observations have been made using the sources 3C 84 and 3C 454·3 at hour angles such that the path length of the radio waves through the atmosphere does not exceed the path length at the zenith by more than a factor of three.

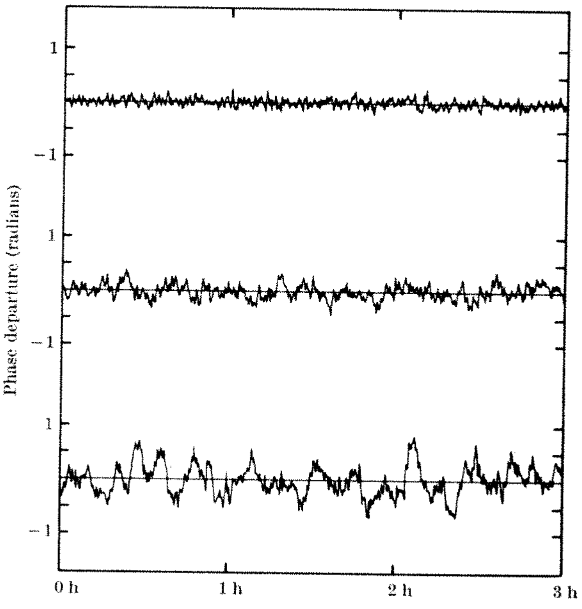

Fig. 2. Typical observations of phase fluctuations from the radio source 3C 84 at 5 GHz during 1969. Top: September 15–16, 2324–0224 UT, separation 47 m, $\sigma(\theta) = 0{\cdot}04$ rad. Centre: June 14, 1145–1445 UT, separation 469 m, $\sigma(\theta) = 0{\cdot}17$ rad. Bottom: June 6, 1012–1312 UT, separation 1,126 m, $\sigma(\theta) = 0{\cdot}38$ rad.

The phase departures observed with the three baselines are generally correlated, and a detailed analysis shows that the departures are caused by a pattern of turbulence which moves across the telescope, affecting each radio path in turn depending on the direction of the wind. The time scale of a phase fluctuation therefore depends on the spatial scale of the refractive index pattern and on the speed with which this is moving relative to the axis of the interferometer. It is typically about 5–10 min when the aerials are separated by a kilometre, as is shown in the records in Fig. 2.

The probability distribution of the phase departures recorded during an observation shows that it is Gaussian; the results have therefore been analysed in terms of the r.m.s. of the recorded phase departure. Although this quantity is determined principally by the variations of refractive index in the troposphere, there are two further contributions for which corrections can be made. The first is a component due to the receiver noise, and the second comes from the phase-sampling procedure. The r.m.s. phase departure resulting from these two effects is typically 0·11 rad, but this value may be found accurately, and hence the r.m.s. phase departure, $\sigma(\theta)$, due to the troposphere alone may be calculated. A further analysis includes the calculation of autocorrelograms for each run, cross-correlograms for pairs of separations which have been observed simultaneously, and frequency spectra. The results of these more detailed analyses will be discussed in a subsequent paper together with the results of some experiments, carried out at larger zenith angles using the source 3C 279, to find the vertical extent of the irregularities.

The observations show a wide range of $\sigma(\theta)$, depending strongly on the time of day and the season. During the summer day-time, large variations of $\sigma(\theta)$ occur from day to day, and these are found to be associated with the weather—the largest values of $\sigma(\theta)$ tending to occur during hot, clear weather conditions. The dependence of $\sigma(\theta)$ on meteorological parameters is complicated, however, and is the subject of a separate paper.

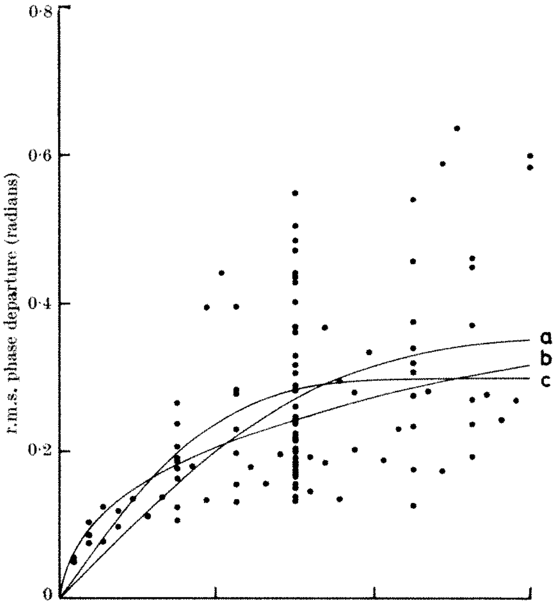

Fig. 3. The effect of aerial separation on the observed r.m.s. phase departures $\sigma(\theta)$ for the summer day-time. The curve *a* represents a Gaussian model having $a=0·36$ rad and a scale size of 800 m, curve *b* has $a=0·44$ rad and a scale size of 2,000 m for an exponential model, and curve *c* represents a Gaussian model having $a=0·30$ rad and a scale size of 500 m.

The results of some 1,473 h of observation during the period January–September 1969 are presented in Figs. 3 and 4. Observations of less than 2 h duration have been rejected from the analysis in order not to restrict the investigation to fluctuations of short period and hence small scale sizes. Values of $\sigma(\theta)$ for each run are plotted as a function of aerial separation in each figure. Observations recorded during the summer day-time, between 0600 UT and 1800 UT from the beginning of April until the end of August 1969, are shown in Fig. 3. Results for (i) summer night-time, (ii) September night-time, and (iii) winter day-time are shown separately in Fig. 4. For comparison some theoretical curves are shown with the summer day-time points and the September night-time points. They have been calculated on the basis of an atmospheric turbulence model assuming either a Gaussian or an exponential autocovariance function of refractive index variations, both of which are often considered in theoretical analyses[5]. The Gaussian autocovariance function for a scale size L gives an r.m.s. phase departure which varies as

$$\sigma(\theta)=\alpha(1-\exp(-X^2/L^2))^{1/2}$$

where α is $\sqrt{2}$ times the r.m.s. departure for a single path through the atmosphere, and X is the distance between the aerials. For an exponential autocovariance function the form of $\sigma(\theta)$ is the same except that the argument of the exponential is $(-X/L)$. These two forms can be distinguished by noting that the rate of change of σ with X as X tends to zero is much larger for the exponential model than it is for the Gaussian model.

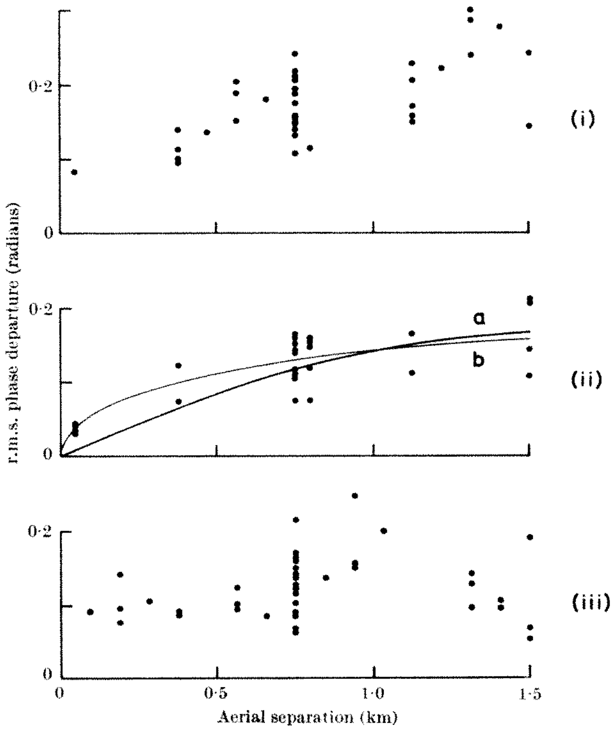

Fig. 4. The r.m.s. phase departure $\sigma(\theta)$ versus aerial separation for (i) summer night-time, (ii) September night-time and (iii) winter day-time. The curve *a* represents a Gaussian model and *b* represents an exponential model. Both curves have $a=0·18$ rad and a scale size of 1,000 m.

During the summer day-time (Fig. 3), $\sigma(\theta)$ varies markedly from day to day and this result is attributed to the wide range of weather conditions which occurs at this time of year. There is a strong dependence of $\sigma(\theta)$ on separation and observations recorded simultaneously at three separations show that the scale size on different days varies from a few hundred metres to several kilometres. Three curves which are compatible with the mean $\sigma(\theta)$ observed at different separations are given to illustrate the wide range of scale sizes and magnitudes of the irregularities which can exist during the summer day-time.

During the summer night-time (Fig. 4 (i)) and throughout the winter, the values of $\sigma(\theta)$ are smaller than those which occur in the summer day-time, and have a much smaller dispersion. During the winter day-time (Fig. 4 (iii)) there is little variation of $\sigma(\theta)$ with aerial separation, indicating that the irregularities have a very small scale size, less than a hundred metres. Observations during the winter night-time indicate that the phase departures are smaller than those occurring in the winter day-time.

A series of observations recorded at night-time during September 1969 is shown in Fig. 4 (ii). For this period the variation of $\sigma(\theta)$ shows less scatter. Two theoretical curves, (*a*) representing the Gaussian model and (*b*) the exponential model, are given for comparison, both having a scale size of 1 km and $\alpha = 0{\cdot}18$ rad. It seems that the exponential model provides the better fit for this set of observations.

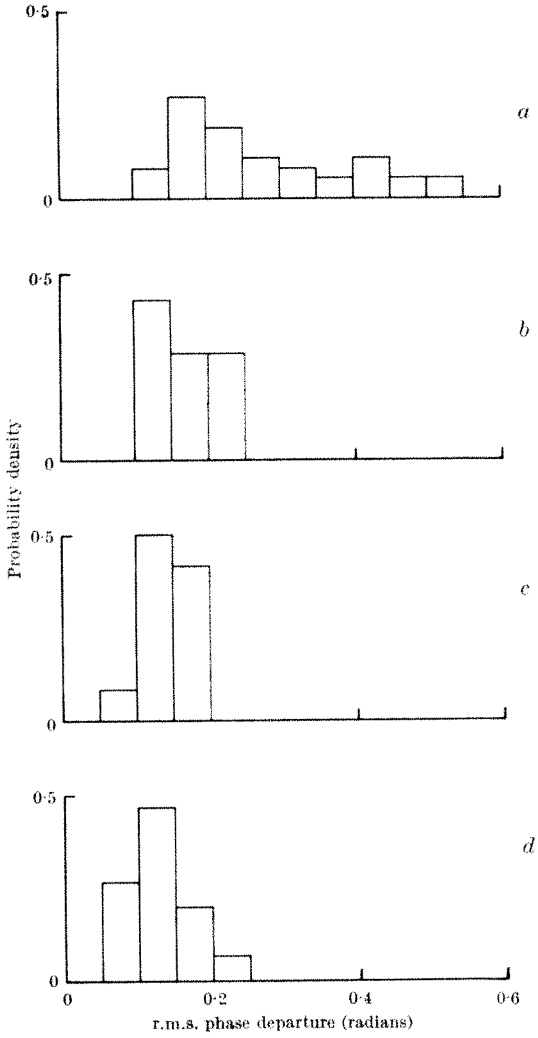

Fig. 5. The observed probability density of r.m.s. phase departure $\sigma(\theta)$ for an aerial separation of 751 m in (*a*) summer day-time, (*b*) summer night-time, (*c*) September night-time, and (*d*) winter day-time.

It is interesting to note that the values of $\sigma(\theta)$ at the smaller separations vary little with the time of day or season, whereas the values at larger separations vary quite radically. An examination of the frequency with which different values of $\sigma(\theta)$ occur is given in Fig. 5, where the probability density of r.m.s. phase departure at a particular separation of 751 m is given for each of the times and seasons considered here. The analysis is again restricted to observations of greater than 2 h duration, of which there are thirty-seven in the summer day-time (Fig. 5*a*); fourteen in the summer night-time (Fig. 5*b*); twelve in the September night-time (Fig. 5*c*); and fifteen in the winter day-time (Fig. 5*d*). The distributions emphasize the outstanding values of $\sigma(\theta)$ which occur at the larger separations during the summer day-time, and show that the probability density is largest near the minimum value of r.m.s. phase departure observed in each case.

Taking the present observations *in toto*, the mean r.m.s. phase departure observed at Cambridge is between 0·1 and 0·2 rad at 5 GHz. For comparison the observations made by Baars and by Basart *et al.* at the National Radio Astronomy Observatory were typically 0·1 rad at 2·7 GHz, which would be about 0·2 rad at 5 GHz. There is no further information for a more detailed comparison.

Discussion

The results, particularly over the period January–September 1969, have given detailed data on the irregularities of the wavefront of 5 GHz radiation passing through the atmosphere. The r.m.s. phase departure is highly variable, but usually increases with baseline, and has a marked dependence on the time of day at the larger separations, particularly during the summer. This result is to be used in a separate paper which discusses the ultimate limitations set both by the atmosphere and by the ionosphere on radio observations of celestial objects from the ground. It turns out that observations in the UK at 5 GHz with radio telescopes having apertures of several kilometres will not be seriously affected for much of the time. Observations at higher frequencies will be possible during the night and particularly during the winter months.

It is possible to use the results of this investigation to predict how the observed refractive index irregularities will influence the behaviour of millimetre-wave satellite communications systems which are proposed for the near future. The principal effect on dish aerials will be a frequency independent variation of the angle of arrival of radio waves rather than a degradation of the beam due to phase irregularities across the aperture. A direct observation of this phenomenon was made by Unger[6] using the Early Bird satellite at 4 GHz, and the 20 m wide horn-reflector aerial at the American Telephone and Telegraph Station near Andover, Maine. About 20 min of data were analysed and the r.m.s. deviation of the angle of arrival was found to be about 2×10^{-5} rad. The present results, taken over a much longer period of time, predict that the variation observed by aerials having apertures of less than a hundred metres in the UK will not change much with season or time of day and will be of the order of 10^{-5} rad r.m.s. Because the phase departures are observed to be normally distributed, the angle of arrival is expected to be within 3×10^{-5} rad of its mean value for 99 per cent of the time. The angle variations will increase rapidly as the elevation angle decreases, however, because of the longer path through the atmosphere, and will be some ten times the zenith value for an elevation angle of 5°. The variations have a time-scale of several seconds and servo-controlled pointing is easily capable of following such deviations. It is concluded therefore that variations in the refractive index of the troposphere will not form a serious hazard to reliable Earth to satellite communications systems as long as the satellite is more than a few degrees above the horizon. The communications systems will, however, still be limited by more serious tropospheric effects such as the absorption and scattering of radio waves by clouds and precipitation.

I thank many colleagues for help and the Science Research Council for a maintenance award.

Level Populations of Excited States of Hydrogen in Gaseous Nebulae

THE radiation from hydrogen atoms which is observed at radio and millimetre wavelengths due to atomic transitions between levels of high quantum number n cannot be accounted for without accurate calculations of the population densities of all the levels[1,2]. In order to interpret the observed intensities[3], and to deduce physical parameters such as temperatures and abundances, accurate calculations of level populations are needed. In gaseous nebulae the physical processes which may populate and depopulate a quantum level are radiative capture and cascade, collisional ionization and three-body recombination, collisional transitions ($n \rightarrow n'$) induced by electrons and protons, and radiative transitions induced by the free-free continuum within the nebula. Calculations have been made over a large range of temperatures and densities and for all n. The results should be much more accurate than any available previously.

Dyson[4] has shown that, for any reasonable emission measure, induced radiative transitions have a negligible effect on the level populations. The cross-sections for n to $n \pm 1$ transitions due to proton collisions have been computed. Their effect is negligible, if $T_e < 10^5$ K, in the region in which populations are not completely determined by collisional processes.

Allowing for the remaining processes, the equation of statistical equilibrium is[5]

$$N_e N_+ \{\alpha_n + C_{i,n}\} + \sum_{n'=n+1}^{\infty} N_{n'} A_{n',n} + \sum_{n'=n_0}^{\infty} N_{n'} C_{n',n}$$
$$= N_n \sum_{n'=n_0}^{n-1} A_{n,n'} + N_n C_{n,i} + N_n \sum_{n'=n_0}^{\infty} C_{n,n'} \quad (1)$$

The symbols are defined by Seaton[5]. Equation (1) may be expressed in terms of b_n factors

$$\sum_{n'=n+1}^{\infty} (A_{n',n} \frac{n'^2}{n^2} e^{x_{n'} - x_n} + C_{n,n'}) b_{n'}$$
$$+ (-\sum_{n'=n_0}^{n-1} A_{n,n'} - \sum_{n'=n_0}^{\infty} C_{n,n'} - C_{n,i}) b_n + \sum_{n'=n_0}^{n-1} C_{n,n'} b_{n'}$$
$$= -\frac{\alpha_n}{n^2} \left(\frac{h^2}{2\pi m k T_e}\right)^{-3/2} e^{-x_n} - C_{n,i} \quad (2)$$

or, more conveniently,

$$\sum_{n'=n_0}^{\infty} K_{n,n'} b_{n'} = L_n \quad (3)$$

The procedure adopted is to solve the set of simultaneous equations of the form

$$\sum_{n'=n_0}^{N} K_{n,n'} b_{n'} = L_n \quad (N > 300) \quad (4)$$

using the matrix condensation technique first suggested by Burgess and Summers[6]. For $n > N$ the solutions are fitted to analytical expressions, subject to the boundary condition that $b_n \rightarrow 1$ as $n \rightarrow \infty$. Allowance is made for transitions from levels above N, by corrections to the condensed form of the matrix K.

The rates of collisional excitations from level n to $n \pm 1$, induced by electrons and protons, are calculated using the impact parameter method of Seaton[7]. Symmetrized binary encounter theory[8] is used for all other collisional transitions and for the ionization rates. Expressions for radiative transition probabilities are given by Baker and Menzel[9], and for radiative recombination rates by Seaton[10]. Accurate Gaunt factors are used throughout[11,12].

This method has several advantages over the differential equation approach[4,5,13]. It avoids having to replace

equation (2) by an approximate, differential form and eliminates the arbitrary lower boundary condition where the solutions are matched to the radiative case. Collisional transitions to any level are included and solutions may be obtained over all n.

Factors b_n and d log b_n/d$_n$ have been computed for a large range of temperatures and densities. Table 1 gives some typical results assuming case B of Baker and Menzel[9]. The important effect of including collisional excitation and de-excitation to any level is illustrated in Table 2. Results obtained allowing for all transitions (columns 2 and 3) are compared with those obtained by the same method assuming *n to n* ± 1 transitions only (columns 4 and 5).

Calculations allowing for all collisional transitions have recently been made by Sejnowski and Hjellming[14], using an iterative method of solution. Our results for the b_n factors are larger than theirs, probably due to differences in the adopted rate coefficients for the collisional processes. I consider that my rate coefficients are more accurate than those of Sejnowski and Hjellming.

A more detailed account and discussion of the results will be published later. I thank Professor M. J. Seaton for introducing me to the problem and for guidance. This work was supported by a Science Research Council grant.

Long Period Oscillations in Rotating Neutron Stars

THEORETICALLY, the structure of a rotating neutron star can support a variety of oscillations which may coexist with and couple to its surface rotation. Because it seems extremely probable that the pulsar period is kept by the rotating surface of a neutron star, the excitation of such modes would give small periodic modulations in observed pulsar frequencies. Most oscillatory modes have relatively high frequencies. But one does exist, unique to a rotating sphere of neutron superfluid, which has a period of about 4 months—close to the "wobble" reported for the period of the Crab pulsar[1]. The frequency of the oscillation mode of the rotating superfluid is insensitive to unknown parameters describing the stellar interior.

A probable neutron star model consists of a solid outer crust[2] surrounding a quantum fluid of nuclear density the main constituent of which is a BCS-type neutron superfluid[3,4]. Its temperature is estimated to be one or two orders of magnitude below the superfluid transition temperature. The crust is rather weakly coupled to the neutron superfluid; in the Vela pulsar the characteristic time for the exchange of angular momentum between the two seems to be a few years[5]. A highly conducting electron–proton sea (the protons are probably superconducting) contributes a few per cent of the interior density and is strongly coupled to the crust (but not to the neutrons) by the strong magnetic field which connects them. For oscillations involving stellar shape or density changes the period $T \lesssim 10^{-3}$ s. Torsional oscillations of the crust[2] have $T \lesssim 10^{-1}$ s. The magnetic coupling between the conducting crust and the core proton–electron sea gives[5] $T \sim 10^{14} B^{-1}$ s; for the magnetic fields usually assumed for pulsars $B \sim 10^9$–10^{12} G, and $T \lesssim 10^5$ s.

Two other kinds of oscillations are possible when the interior superfluid is rotating. One is the classical torsional type oscillation of a uniformly rotating fluid. The characteristic period for such a mode is $\sim \pi\Omega^{-1}$ where Ω is the fluid angular velocity. For all known pulsars such oscillations have $T \lesssim 0{\cdot}3$ s. The other fluid motion, unique to a superfluid, depends on the quantization of its microscopic motion. A rotating superfluid moves irrotationally: it can mimic rigid body rotation through a paraxial array of moving quantized vortex lines[6–8]. The fluid velocity satisfies $\boldsymbol{\nabla} \times \mathbf{v} = 0$ except within the core of each vortex. For rotating interiors of neutron stars the core radius[9] $\xi \sim 10^{-12}$ cm and the separation between quantized vortex lines is of order 10^{-2} cm. When averaged over many vortex lines the average fluid velocity $\langle \mathbf{v} \rangle$ can satisfy the usual relation for rigid rotation: $\boldsymbol{\nabla} \times \langle \mathbf{v} \rangle = 2\boldsymbol{\Omega}$. In the corotating frame of an axially spinning cylinder the free energy of a contained superfluid is minimized by a regular (triangular) lattice array at rest with respect to the cylinder walls[10]. Such a vortex array admits two kinds of oscillations. In the first the vortex lines bend; for wavelengths large compared with the intervortex spacing, the frequencies of such oscillations $\sim 2\Omega$, just those expected for a classical fluid. The second mode of vibration of the vortex lattice consists of a purely axial movement of the vortex lines[10,11]; each vortex line remains parallel to the cylinder axis, but there is a redistribution of density of vortices and superfluid angular momenta.

The equation of motion of the vortex lattice for such motions (in the corotating frame) is given by[10]

$$\frac{1}{c_V^2}\,\frac{\partial^2}{\partial t^2}\,\mathbf{s} - \nabla^2 \mathbf{s} = 0 \qquad (1)$$

where $\mathbf{s}(\boldsymbol{\rho},t)$ specifies the parallel displacement of that vortex line whose normal position is $\boldsymbol{\rho}$ from the cylinder axis. The wave velocity is

$$c_V = \frac{1}{2}\left(\frac{\hbar\Omega}{\hat{m}}\right)^{\frac{1}{2}} \qquad (2)$$

which is approximately the intervortex spacing times Ω. The mass $\hat{m}$ is that of the equivalent boson in the BCS model of a fermion superfluid. For the neutron star interior $\hat{m}$ equals twice the neutron mass. Dyson (personal communication) has shown that the lattice vibrations must satisfy the condition $\boldsymbol{\nabla} \times \dot{\mathbf{s}} = -2\Omega \boldsymbol{\nabla} . \mathbf{s}$. Then the lowest admissible mode of vortex lattice motion described by equation (1) is

$$\mathbf{s} = A J_1(k\rho)\left[\cos \omega t\, \boldsymbol{\rho} + \frac{2\Omega}{\omega}\sin \omega t\, \hat{\boldsymbol{\varphi}}\right] \qquad (3)$$

with

$$\omega = k c_V \qquad (4)$$

The associated oscillation of averaged fluid motion is azimuthal. In the rotating reference frame

$$\langle \mathbf{v} \rangle = 2A\Omega J_1(k\rho)\cos\omega t\,\hat{\boldsymbol{\phi}} \tag{5}$$

The appropriate boundary condition depends somewhat on the crust-superfluid coupling at the interface. But because typically the crust has about 10^{-2} the moment of inertia of the neutron superfluid contained within it, only a small part of the angular momentum of the core should be transferred to it during an oscillation no matter what the boundary is like. When transfer of angular momentum across the interface is neglected, the wave number k is determined by

$$k\int_0^R r^2 J_1(kr)\mathrm{d}r = R^2 J_2(kR) = 0 \tag{6}$$

Then for the fundamental oscillation mode $kR \sim 5$ and equations (2) and (4) give for the oscillation period

$$T = \frac{4\pi}{k}\left(\frac{\hat{m}}{\hbar\Omega}\right)^{\frac{1}{2}} \sim \frac{140\,R}{(\Omega)^{\frac{1}{2}}}\ \mathrm{s} \tag{7}$$

for R the neutron star radius, in cm and Ω its angular frequency in rad s^{-1}. Almost all models give $R \sim 10^6$ cm. Then for the Crab pulsar, with $\Omega \sim 2\times10^2\ \mathrm{s}^{-1}$, $T \sim 4$ months, near that reported for the "wobble"[1]. A similar mode excited in the Vela pulsar would be expected to have a somewhat longer period (~ 7 months) because its frequency is about three times less than that of the Crab.

The oscillatory superfluid vortex mode will be coupled to the crust by two mechanisms: (*a*) the transfer of angular momentum directly through the crust-superfluid boundary region; (*b*) the interaction, throughout the entire superfluid, between the normal neutrons inside the vortex cores and the degenerate electron sea which pervades the core[5]; this transfers angular momentum between the neutrons and the electrons and thereby to the conducting crust which is strongly coupled to the latter by magnetic fields.

Any sudden (on a time scale of months) movement of the crust will excite the slow superfluid vortex mode (as well as higher ones). In the case of Vela the time scale for crust–core coupling by mechanism (*b*) has been estimated to be a few years[5]. Because it is directly proportional to the number of vortex lines, to Ω that is, and inversely proportional to the square of the core temperature it is presumably much stronger for the faster and younger (hotter) Crab. (The Vela analysis applied to the small jump $\Delta\Omega/\Omega$ of 4×10^{-9} reported for the Crab pulsar by Boynton *et al.* at the Princeton pulsar symposium suggests a time scale of a week.) Mechanism (*b*) chiefly will be effective in sharing any change in angular speed between the core and the crest. It will also damp variations in $\boldsymbol{\nabla}\times\langle\mathbf{v}\rangle$ within the core but probably on a very much longer time scale because of the very large core relative to crust inertia[5]. Thus the period of core rotational oscillation agrees with that reported if the neutron core is superfluid and appropriate mechanisms exist to couple it to the crust motion. For sufficient core–crust coupling a sudden change in crust motion[12,13] will excite core motions the relative amplitude of which is less than that of the crust by the ratio of the magnetically coupled crust—electron–proton sea moment of inertia to that of the core, typically $\sim 10^{-2}$. Because the reported Crab period "wobble" gives a periodic variation in crust Ω of 1 in 10^{10}, a small starquake which causes a sudden jump in crust Ω of 1 in 10^8 (ref. 9) may be sufficient to leave a fundamental core vortex mode oscillation of the required magnitude after other transients have damped.

A more definitive analysis should substitute spherical for cylindrical geometry, include radial density variation of neutron stars, and offer a quantitative description of core–crust coupling and damping.

I thank Professor E. Spiegel for his interest and Dr P. Hohenberg and Professors J. Luttinger, D. Pines and L. Woltjer for conversations. I also thank Professor Freeman Dyson for his generous counsel. This research was supported in part by the US National Science Foundation.

Apparent Periodicities in the Redshifts of Quasi-stellar Objects

COWAN[1] has applied the method of power spectrum analysis to the distribution of redshifts of quasi-stellar objects and has found several peaks in the power spectrum which, if real, would correspond to periodicities in the distribution of QSO redshifts. This letter points out that the distribution of power levels in his Fig. 1 is not significantly different from what would be expected from the analysis of purely random noise.

If a power spectrum analysis is applied to purely random (white) noise, the distribution of power levels is expected to be a χ^2 distribution with two degrees of freedom. A proof of this is given by Jenkins and Watts[2]. It can also be seen from the fact that the real and imaginary parts of a Fourier transform are linear functions of the data. If the data consist of random fluctuations, then these linear functions will also show random fluctuations which are very nearly normal, by virtue of the central limit theorem. The power, which is the sum of the squares of the real and imaginary parts, has the distribution of the sum of the squares of two normal variates, that is, the χ^2 distribution with two degrees of freedom. The analytic expression for this distribution, $F(\chi^2)$, is

$$F(\chi^2)\,\mathrm{d}\chi^2 = \tfrac{1}{2}\,\mathrm{e}^{-\frac{1}{2}\chi^2}\,\mathrm{d}\chi^2$$

which is normalized so that its integral is unity. The mean value is 2. This distribution function is plotted as the solid line in Fig. 1. Clearly it has quite a long "tail" at large values of χ^2. It would not be surprising, therefore, to find a few points corresponding to quite high power levels in the spectrum of random noise.

I have taken Cowan's Fig. 1 and have attempted to count the relative numbers of points in the power ranges (0, 0·1), (0·1, 0·2), (0·2, 0·3), (0·3, 0·4), (0·4, 0·5). In doing this, I have been guided by the intrinsic width of his peaks as regards the total number of points to count. In the ranges listed I found 14, 9, 5, 3 and 0 points, respectively. To enter these points on Fig. 1 it is necessary to establish the scale of the abscissa, that is, to find the constant a such that $P = a\chi^2$, where P is the measured power level. There are at least three possible ways of doing this: (i) we could equate the mean power level with the mean, 2, of the χ^2 distribution; (ii) we could fit the fraction of power in the low power levels to the theoretical curve; (iii) we could fit the logarithmic derivative of the distribution to the theoretical slope $\mathrm{d}\ln F/\mathrm{d}\chi^2 = -\frac{1}{2}$. Because of the long tail of the χ^2 distribution, it is possible that we may have missed some points at even

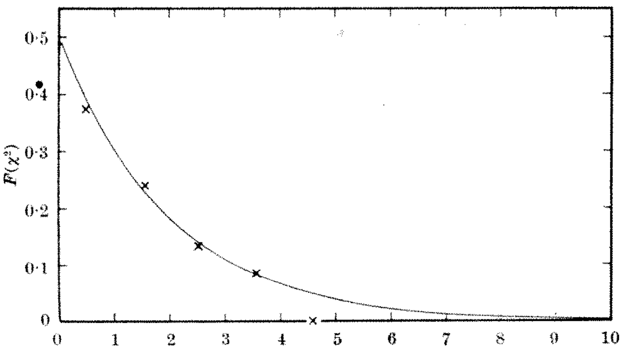

Fig. 1. Theoretical (line) and observed (crosses) distribution of power levels in analysis of QSO redshift periodicities.

higher powers than those calculated. Such an incompleteness in the data will affect both the estimate of mean power and the calculation of the fraction of the total power at low power levels. It does not affect the logarithmic derivative, however. For this reason I have used method (iii) to find a mean value of $a = 0{\cdot}098 \pm 0{\cdot}014$. With this value of a, we can calculate that the fraction of points lost at power values greater than 0·5 should be 0·078, so that, whereas only thirty-one power points were counted, there should have been thirty-eight. Hence the counted points represent fractions 0·37, 0·24, 0·13, 0·08, 0·00 at abscissae 0·51, 1·53, 2·55, 3·57, 4·60, respectively. These points are plotted as crosses on Fig. 1.

There seems to be no significant departure from the distribution expected for a random distribution of data points. Of course, like any statistical test of significance, this is one-way; it allows us to accept the hypothesis that the original data were random, but does not necessarily reject the hypothesis that the data were non-random.

If the original data were random, then probably seven or so more points could be discovered in the power spectrum at still higher power levels.

Since this note was prepared, the article by Plagemann, Feldman and Gribbin[3] has appeared, reaching essentially the same conclusions. I believe that the presentation of the expected power levels from random noise in terms of the χ^2 distribution in Fig. 1 is an additional point of interest which is not immediately clear from their results.

Origin of the Optical Polarization in the Nucleus of NGC 1068

MEASUREMENTS of the degree of polarization of the nuclear region of NGC 1068 by Kruszewski[1] and Visvanathan and Oke[2] show that the degree of polarization increases with decreasing diaphragm size, which suggests that the polarization is produced in and close to the nucleus and that the radiation contributed by other parts of the galaxy is unpolarized. In order to find what process or processes are responsible for the optical radiation from the nucleus it is important to determine the intrinsic polarization of the nucleus. To do this we require the dilution factor, D, which is the ratio of the integrated surface brightness of all the radiation from the galaxy within the diaphragm to that of the nucleus. The distribution of surface brightness across the galaxy has been measured with a resolution of 2·6 square seconds by van Houten[3]; he has corrected the data for the smoothing introduced by finite angular resolution and by atmospheric dispersion to give a resolution of 1 square second. At this resolution the nucleus has a surface brightness $S = 12\overset{\mathrm{m}}{.}77$ (square s)$^{-1}$; at $r = 1$ s, $S = 16\overset{\mathrm{m}}{.}35$ (square s)$^{-1}$. Walker[4] places an upper limit of 1·5 s on the nuclear diameter, $2r_{\mathrm{N}}$, corresponding to a nuclear area of 1·8 square s; we shall assume these values in what follows.

We assume circular symmetry and $S(r)$ as the surface brightness at distance r s from the nucleus. The degree of polarization is P_{N} at $r < r_{\mathrm{N}}$, where r_{N} defines the edge of the nucleus, and at $r > r_{\mathrm{N}}$ the degree of polarization is zero. The observed flux measured with a diaphragm of radius r_{D} s is then

$$\begin{aligned} F &= \int_0^{r_{\mathrm{D}}} S(r)\ 2\pi r dr \\ &= \pi r_{\mathrm{N}}^2 < S_{\mathrm{N}}(r) > + (\pi r_{\mathrm{D}}^2 - \pi r_{\mathrm{N}}^2) < S_{\mathrm{G}}(r) > \end{aligned}$$

where suffices N and G refer to the nucleus and the remaining part of the galaxy respectively. The fraction of the observed flux which is plane polarized is

$$\begin{aligned} P_{\mathrm{OBS}}\ F &= \int_0^{r_{\mathrm{D}}} p(r)\ S(r)\ 2\pi r dr \\ &= \pi r_{\mathrm{N}}^2\ P_{\mathrm{N}} < S_{\mathrm{N}}(r) > \end{aligned}$$

Thus

$$P_{\mathrm{N}} = D\ P_{\mathrm{OBS}}$$

where the dilution factor is

$$D = 1 + \frac{r_{\mathrm{D}}^2 - r_{\mathrm{N}}^2}{r_{\mathrm{N}}^2}\ \frac{< S_{\mathrm{G}}(r) >}{< S_{\mathrm{N}}(r) >}$$

We shall compute D for the recent observations of Kruszewski[1] who used $r_{\mathrm{D}} = 4{\cdot}6$ s. Because $r_{\mathrm{D}}^2 \gg r_{\mathrm{N}}^2$ we find, using van Houten's data, that

$$D = 1 + \frac{\int_{r_{\mathrm{N}}}^{r_{\mathrm{D}}} r\ S(r)\ \mathrm{d}r}{\int_0^{r_{\mathrm{N}}} r\ S(r)\ \mathrm{d}r} = 16{\cdot}9$$

We have used an upper limit to r_{N} so that strictly $D \geq 16{\cdot}9$.

The photometric results of van Houten for NGC 1068 are given in the international photographic magnitude system which is close to the B system. Thus the dilution factor is relevant to the polarization observations in B. Kruszewski finds $P_{\mathrm{OBS}}(B) = 2{\cdot}36$ per cent and thus

$$P_{\mathrm{N}}(B) = 39{\cdot}9 \text{ per cent}$$

It is interesting to note that if this dilution factor were relevant to the observations in U for which Kruszewski finds $P_{\mathrm{OBS}}(U) = 5{\cdot}12$ per cent, the $P_{\mathrm{N}}(U) = 86{\cdot}5$ per cent and the polarization in U would be almost complete. Further note that $P_{\mathrm{N}}(B)$ cannot exceed 100 per cent and thus we can determine the limiting value $(r_{\mathrm{N}})_{\mathrm{MIN}}$ which produces $P_{\mathrm{N}}(B) = 100$ per cent: we find $(r_{\mathrm{N}})_{\mathrm{MIN}} = 0{\cdot}46$ s corresponding to a linear radius of about 25 pc.

The clues to the origin of the optical radiation from the nucleus are (*a*) $P_{\mathrm{N}}(B) \sim 40$ per cent is very high, (*b*) P_{N} depends strongly on wavelength[1] and (*c*) the radiation is very blue[4]. Before allowance was made for the dilution factor it seemed perfectly reasonable to suggest[4] that a degree of polarization ~ 0 to 5 per cent should be produced by optical synchrotron radiation. To explain 40 per cent polarization is much more difficult, however: not only is a strong magnetic field ($> \sim 10^{-3}$ G) required but also it must be well ordered over dimensions ~ 50 pc, the minimum diameter of the nucleus. Moreover, to obtain maximum linear polarization the magnetic field should be normal to the line of sight, but this would require that the nuclear magnetic field is approximately in the plane of the galaxy because the line of sight is nearly normal to the plane. If the required strong magnetic field were produced by dynamo action in a rotating nucleus[5], we would require that the axis of rotation of the nucleus be in the plane of the galaxy, an unlikely occurrence. An alternative possibility is that the dust surrounding the nucleus, which is required to explain the infrared radiation[6], could be strongly aligned and could produce the strong polarization. For perfectly aligned grains either of iron or graphite[7] a maximum polarization of only 25 to 30 per cent can be obtained, however.

A further possibility deserves consideration. If the nucleus is surrounded by a dense shell of grains, as suggested by Rees *et al.*[6], then much of the light from the nuclear region may be radiation scattered by the grains. Given a model of the dust shell in which the grain density decreases outwards so that most of the scattering is at phase angles of 90° ± 35° and given very small grains which scatter according to Rayleigh–Gans theory, so that the degree of polarization of the first order scattered light lies between 50 and 100 per cent, it is conceivable that $P_N \sim 40$ per cent might be explained. The observed blueness and the observed increase of $p_{\rm OBS}$ with decreasing wavelength are both consistent with this explanation.

Cassiopeia A Absorption Spectrum and the Interarm Medium

A MEASUREMENT of the neutral hydrogen absorption spectrum of the Cassiopeia A radio source can in principle give information about the interarm regions of the Milky Way because this source lies in (and probably on the far side of) the Perseus arm. Neutral hydrogen lying in the region between the local arm and the Perseus arm may therefore be detectable in absorption as well as in emission. A combination of the emission and absorption data can give the spin temperature of the interarm gas (for example, see ref. 1). During the Conference of Young European Radio Astronomers at Jodrell Bank in June 1969, I was encouraged to make these measurements in discussions with Dr U. Mebold. This report describes measurements of the Cassiopeia A spectrum made with higher precision than those already published[2–4].

Observations were made on August 16, 1969, with the 250-foot radio telescope which had a primary halfpower beamwidth for this experiment of 13′ × 18′ arc. It has a further response in a beam 30′ arc in radius which contains about 30 per cent of the power. The new 256 channel digital autocorrelation spectrometer was used to measure neutral hydrogen spectra on and near Cassiopeia A. A 1·25 MHz overall bandwidth was chosen to give adequate base level in the spectra on either side of the neutral hydrogen features. The effective halfpower resolution bandwidth was 9 kHz.

A calculation of the spin temperature of neutral hydrogen by this method requires first a good estimate of the emission spectrum interpolated to the position of the source. Spectra were obtained on a grid of points surrounding Cassiopeia A and the results of averaging spectra at different distances from Cassiopeia A are shown in Fig. 1. Those at 39′ arc (Fig. 1*a*) varied by ± 2·5 K at the minimum near 110 kHz, while those at 19′ arc (Fig. 1*b*) varied by ± 1·1 K, indicating the improvement in accuracy of the interpolation over smaller distances. It should be noted that the spectra obtained at 19′ arc contained 1·2 per cent of the Cassiopeia A absorption spectrum; this has a negligible effect on the part of the spectrum near 110 kHz—the actual "expected" emission profile at the position of Cassiopeia A when corrected for this effect is 0·1 K higher than shown in Fig. 1*b*. The similarity of Figs. 1*a* and 1*b* in the frequency interval 90 to 130 kHz relative to the l.s.r. would indicate that the expected profile in the range is accurate to better than 2 K.

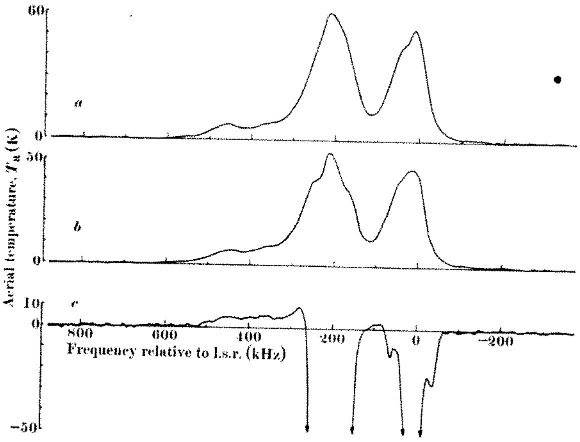

Fig. 1. *a*, Average of four spectra taken on a grid spaced 39′ arc from Cassiopeia A; resolution is 9 kHz; *b*, average of four spectra taken on a grid spaced 19′ arc from Cassiopeia A; note that 1·2 per cent of the absorption spectrum is included; *c*, spectrum observed on the position of Cassiopeia A.

The true absorption spectrum of Cassiopeia A is obtained by subtracting the expected emission profile from the profile observed at the source position (Fig. 1*c*). The expected profile was that shown in Fig. 1*b*, and corrected for the small amount of absorption profile contained in it. Fig. 2*b* gives our best estimate of the true absorption spectrum as obtained with a frequency resolution of 9 kHz. With this resolution the narrow absorption features are not completely resolved although the interarm region which we are interested in as represented by the frequency interval 90 to 130 kHz is completely resolved. Fig. 2*c*, which gives the central part of the spectrum with a resolution of 4·5 kHz, illustrates this point. No attempt has been made at an absolute determination of the optical depth scale, for it is difficult and not necessary for the present purpose. I have taken the absorption at the deep feature in the Perseus arm to be 99·9 per cent (optical depth = 7·0) as given by Shuter and Verschuur.

If we consider that the part of the spectrum near the position of the emission minimum between the local and Perseus arms is representative of the interarm medium, we can derive the spin temperature T_s of this medium from the ratio $T_s = T_b/\tau$, where T_b is the brightness temperature of the emission taken as 1·2 T_a and τ is the optical depth in absorption. The minimum values of T_b and τ are 12·1 ± 2·5 K and 0·022 ± 0·008 respectively. The errors given take account of the interpolation in position for T_b and the assessment of the baseline for the spectra; the error contribution by noise fluctuations in the receiver is small in comparison with these values. It will be noted that the T_B and τ curves are not the same shape in the frequency interval 90 to 130 kHz and in particular the minima are displaced relative to one another by about 15 kHz. This will mean that our derived T_s varies with

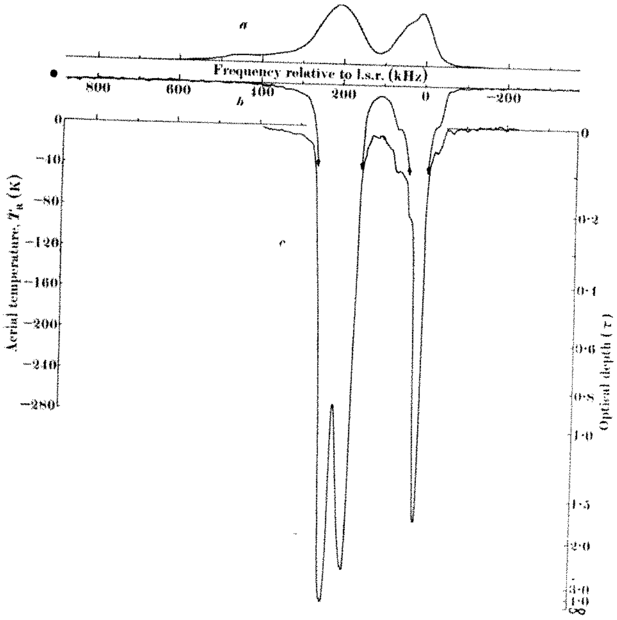

Fig. 2. *a*, The "expected" emission spectrum of Cassiopeia A. Resolution is 9 kHz; *b*, true absorption spectrum of Cassiopeia A with a resolution of 9 kHz; *c*, true absorption spectrum of Cassiopeia A with a resolution of 4·5 kHz.

frequency. Our estimate of T_s including the uncertainties given is $T_s = 540 \pm 230$ K.

An independent assessment of both the emission and absorption spectra was made from the data obtained during observations[5] of the Zeeman splitting of the Cassiopeia A absorption spectrum using the Mark II telescope with a beam of half intensity width 36′ arc and low sidelobes (less than 1 per cent). Although the beamwidth is more than twice that of the 250 ft telescope its sidelobe structure is very much cleaner and will have less effect on the emission spectrum (the true absorption spectrum is not affected by the sidelobe structure). The minimum T_B in the range 90 to 130 kHz was 10·8 K, which is within the uncertainty assigned from data from the 250 ft telescope. τ was estimated to be $0{\cdot}014 \pm 0{\cdot}010$, again within the errors given.

I conclude that it is possible with the present techniques to measure the "interarm" absorption spectrum of Cassiopeia A to an accuracy rather better than 1 per cent when account is taken of all the likely sources of error. A marginally significant absorption was found at frequencies which might reasonably be assigned to the interarm medium and this leads to an estimate of the spin temperature of 540 ± 230 K on certain simplifying assumptions. The first assumption is that this part of the spectrum is indeed the result of interarm gas rather than the high dispersion of wings of the local and Perseus arm gas. And the second is that the interarm gas is uniformly distributed; if this is not so, the value of T_s derived from the observed values of T_b and τ could be uncertain by a factor of at least two either way, for example if the scale size was comparable with the angular diameter of Cassiopeia A.

Thermal History of the Moon

I HAVE already used[1] the creep behaviour of the mascons in my model of their origin and morphology[2] to set limits on the internal temperature of the Moon at present, former and primordial epochs. Results for the present are consistent with the upper limit obtained by Ness[3] from the electrical conductivity of the Moon implied by magnetometry in space. The purpose of this article is to use the approximation to the central temperature set by the result of Ness in order to correct previous solutions[4–7] of the heat-conduction equation, to infer possible thermal histories consistent with the present thermal regime.

The thermal history of a planetary body after full accretion is controlled by the internal heat arising from radioactive decay, as specified by the equation of heat conduction. For simplicity, the total rate Q of production of heat per unit mass will be assumed uniform throughout the body at a particular time. The thermal parameters of the body will be taken as constant.

Under the last restrictions, the equation of heat conduction has been solved by Lowan[8]. The solution consists of two parts, $T = T_{\text{par}} + T_{\text{hom}}$, where T_{par} is a particular solution of the full equation involving Q and T_{hom} is the solution of the homogeneous equation dependent on the initial temperature distribution. As a simplification, it will be assumed that the initial temperature at the epoch of origin 4·5 Gyr ago equals 0° C throughout the body. In this case T_{hom} vanishes for all time and the solution becomes $T = T_{\text{par}}$.

Let $T^*(r)$ be such a solution at the present epoch as a function of the radial distance r in the body for particular values μ_i^* of the present abundances of isotopes (designated by i). For another choice $\mu_i = f\mu_i^*$ of abundances, where f is a constant, the ratios of abundances of different isotopes remain invariant. From the equation of heat conduction, one verifies that the solution $T(r)$ corresponding to the values of μ_i is $T = fT^*$, for the particular solutions. One has

$$f = \mu_i/\mu_i^* = T_c/T_c^* \tag{1}$$

immediately in terms of the central temperatures T_c and T_c^* for values of μ_i and μ_i^*, respectively.

The current density J of heat flow from the body is $J = -K(\partial T/\partial r)_0$ in terms of the thermal conductivity and gradient at the boundary. Under the assumption of an equilibrium condition in which all the heat generated at the present time reaches the surface, J is related to the heat production Q by

$$SJ = MQ \tag{2}$$

where S is the surface area and M the mass of the body. While the values of μ_i for the significant radioactive species show large variations for rocks found on the Earth's surface, the Wasserburg ratios Th/U and K/U of the concentrations are relatively constant for different rocks[9]. For average values of these ratios, the abundance μ_U of uranium in the Wasserburg model is fixed by demanding that Q in equation (2) yield the observed average heat flow J over the Earth. This procedure fixes the value of μ_i for ^{238}U, ^{235}U, ^{232}Th and ^{40}K for the Wasserburg model of terrestrial abundances. In what follows, the isotope ^{235}U will be ignored, in view of its relatively small contribution to the heat budget.

The abundances of radioactive elements for a homogeneous Earth on the Wasserburg model[9] are given in Table 1, as determined by MacDonald[10] for the Wasserburg ratios[9] Th/U = 3·7 and K/U = 1×10^4. In Fig. 1, the corresponding solution of the equation of heat conduction for the temperature is shown as a function of depth at the present time from results of Fricker *et el.*[6] for a Moon initially at 0° C with uniformly distributed radioactivities. Also shown is the curve of MacDonald[5] for an initially cold Moon heated by chondritic radioactivity.

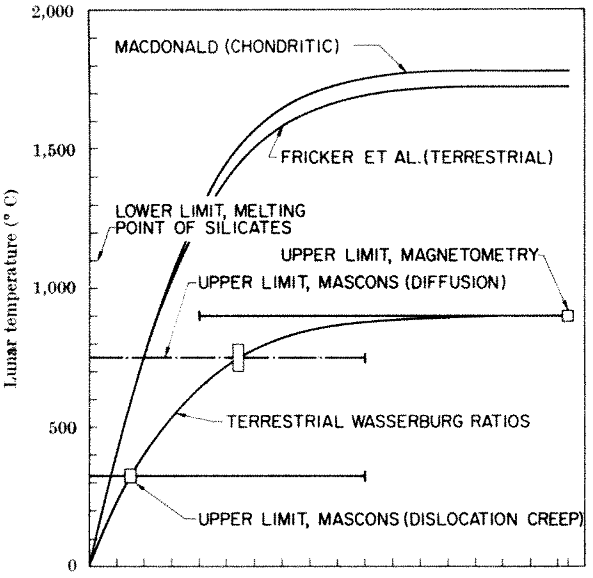

Fig. 1. Present temperature of the Moon as a function of depth for terrestrial Wasserburg ratios, scaled from the solution of the equation of heat conduction by Fricker *et al.* for a terrestrial composition (as shown) to correspond to the central temperature set by the magnetometric result of Ness. Coordinates of the lunar asthenosphere on the hypotheses of dislocation and diffusion creep are indicated by rectangles of error.

The upper limit 900° C on the internal temperature from magnetometry in space (indicated by the horizontal bar in Fig. 1) will be taken as an approximation to the central temperature of the Moon. By means of equation (1), one can then correct the curve of Fricker *et al.* as shown to this central temperature for the same Wasserburg ratios (for $f = 0{\cdot}46$). The lunar temperature on this basis for terrestrial Wasserburg ratios at the present time appears as a function of depth in Fig. 1; values are approximately one-half the corresponding ones of Fricker *et al.* for radioactivity specified by MacDonald[10]. In view of the lower limit on the melting point of silicates indicated, melting at any depth in the Moon is not permitted at the present time by this result.

Lunar temperatures in the past for terrestrial Wasserburg ratios are shown as a function of time from the epoch of origin 4·5 Gyr ago by the curves in Fig. 2 for different depths, computed in the same manner as that of Fig. 1 from data of Fricker *et al.* for a Moon initially at 0° C with uniform radioactivity. Obviously, these results do not permit melting in the lunar interior at any epoch. On the other hand, the curves of Fricker *et al.* for the Wasserburg terrestrial model, as shown, demand internal melting for an extended period in the past (over 1 Gyr at 1 to 3 Gyr ago) for depths up to 150 km from the surface.

The abundances of the radioactive elements in the Moon implied by equation (1) from the curve of Fig. 1 for terrestrial Wasserburg ratios are shown in Table 1; they are somewhat less than one-half the corresponding values of MacDonald[10]. Recently Hanks and Anderson have emphasized that the procedure of MacDonald in using equation (2) to fix the concentration of U in the Earth by means of the average heat flow probably results in a serious overestimate, because he suppressed such other sources of heat in the calibration as terrestrial core formation and high initial temperature[11]. The determination of radioactivity in the continental crust and oceanic rocks by Heir and Rogers[12], the recent measurements on oceanic lherzolites by Wakita *et al.*[13], and new evidence from continental heat flow by Roy *et al.*[14] all point to radioactive concentrations considerably lower than the values of MacDonald in Table 1. From these data, Hanks and Anderson have constructed a preferred model (their Model IV) for averaged continental and oceanic radioactivity in the Earth, as shown in Table 1. These values are roughly one-half those of MacDonald, and the values of this work for the Moon are in fairly good agreement with them.

Table 1. ABUNDANCES OF RADIOACTIVE ELEMENTS FOR A HOMOGENEOUS EARTH AND MOON IN g/g

Nuclide	Earth (MacDonald)	Moon (this work)	Earth (Hanks and Anderson)
^{238}U	$3{\cdot}52 \times 10^{-8}$	$1{\cdot}5 \times 10^{-8}$	$1{\cdot}87 \times 10^{-8}$
^{232}Th	13×10^{-8}	6×10^{-8}	$5{\cdot}91 \times 10^{-8}$
^{40}K	$4{\cdot}2 \times 10^{-8}$	2×10^{-8}	$1{\cdot}14 \times 10^{-8}$

I have inferred upper limits to the internal temperature of the Moon in the layer of low strength (the asthenosphere) from the creep behaviour of the mascons[1]. For the two possibilities of diffusion and dislocation creep, the intersections in Fig. 1 of the horizontal bars for the temperature limits with the curve of lunar temperature against depth permit one to specify approximately the pertinent asthenosphere depths at present, as indicated by the rectangles delineating limits of error. It is obvious from Fig. 2 that the creep of the mascons could be controlled by diffusion only if they were formed less than about 1 to 1·5 Gyr ago, in which case the asthenosphere would lie near or above the Moon's centre. Such a young age seems unreasonable in view of my prior results[1,2]. Hence one must infer that mascon creep most likely is controlled by dislocation motion—contrary to the conclusion of my earlier paper[1].

Table 2 shows values of the surface temperature gradient, the corresponding heat flow J for a mean conductivity[15] and the heat production Q from equation (2) for the Moon at the present time, for terrestrial Wasserburg ratios. For the Earth, the surface temperature gradient is an average for continental areas[16], reflecting the high central temperature of about 6,000° C, as estimated by me[17] and others[18]. Values from MacDonald[10] are shown for J and Q; the latter exceeds the tabulated lunar value by a factor roughly two, in agreement with the contention of Hanks and Anderson[11] that it is too high for the Earth by about this factor.

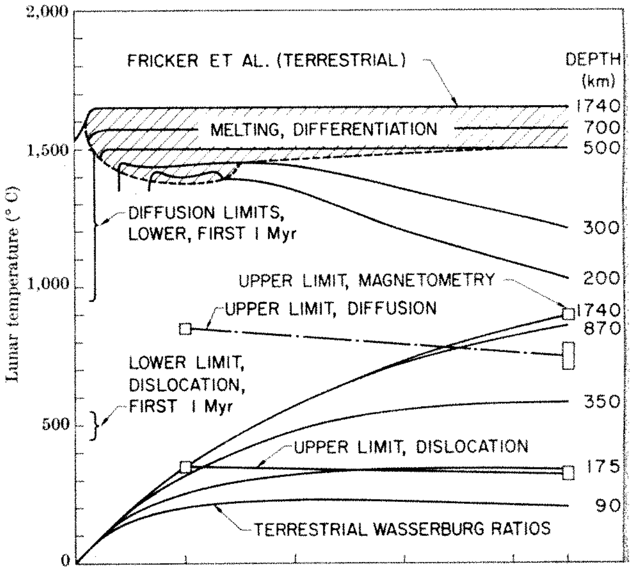

Fig. 2. Temperatures of the Moon at different depths as a function of time in the past for terrestrial Wasserburg ratios, scaled from solutions of the equation of heat conduction by Fricker *et al.* for a terrestrial composition to correspond to the central temperature set by the magnetometric result of Ness. Results of Fricker *et al.* for an initially hot Moon, including effects of melting and differentiation, are shown for comparison. Upper limits on the asthenosphere temperature at the present and former epochs are indicated by lines, and lower limits for the primordial epoch by brackets.

Estimates of the initial temperature near the surface toward the end of the main phase of accretion for bodies of lunar and terrestrial size vary from about 100 K to over 1,000° C. This procedure of adopting an initial temperature as a boundary value on the equation of heat conduction may be merely an ingenuous artifice which can mislead, as emphasized recently by Hanks and Anderson[11] in a discussion of the possibly very significant effects of the early accretion stage on the later thermal evolution of the Earth.

Table 2. PHYSICAL PARAMETERS AT THE PRESENT TIME ASSOCIATED WITH THE THERMAL HISTORY OF THE MOON, COMPARED WITH THOSE FOR THE EARTH

Body	Model	Surface gradient $-(\partial T/\partial r)_0$ (°C km^{-1})	Heat flow J (erg cm^{-2} s^{-1})	Heat production Q (erg g^{-1} yr^{-1})
Moon	Earth Wasserburg ratios	2·1	6·5	1·1
Earth	Observational	17·9	63·9	2·55

My theory of a former atmosphere and hydrosphere of the Moon presupposes a relatively brief episode of moderate internal heating near the epoch of origin to release the volatiles, by the accretion mechanism or by decay of nuclides of short lifetime[2,19]. Thus it is a satisfying feature of my theory of creep behaviour of the mascons[1] that it requires an elevated initial temperature near the surface to permit isostatic compensation within a time in the range 1 kyr to 1 Myr from the Moon's origin. The range of the lower limits to the temperature in the lunar asthenosphere at this pristine epoch is indicated by a bracket in Fig. 2, as demanded by dislocation creep of the mascons.

Lowan's solution[8] T_{hom} specifying the decay of an initial temperature distribution cannot be used directly with temperature data from the primordial mascon creep to obtain a realistic description of the early thermal history. First, the mascon data yield a lower limit only to the temperature[1]. Second, they refer to the unknown depth of the primordial asthenosphere, on which the only datum is that it probably lay close to the pristine level of mean density[2]. Finally, this procedure would ignore the possibility of significant heating by short-lived radioactive nuclides[2,19] (such as ^{26}Al).

The most one can assert is that the temperature for the primordial asthenosphere lay in the range of about 500° C to the melting point of silicates, from Fig. 2. Thus the mascon data yield primarily clues to the early thermal history.

In view of the possible thermal history found, the conclusion of my earlier paper[1] stands, that any extensive lava flow present on the lunar surface must have erupted in the early history, at least 3·5 Gyr ago, roughly. The potassium–argon ages ($3 \cdot 0 \pm 0 \cdot 7$ Gyr) found in Apollo 11 samples for the igneous crystalline rocks are consistent with this estimate[20] (because they represent the time from last melting).

The basic procedure used here is to calibrate the average abundances of radioactive isotopes throughout the Moon by means of the central temperature inferred from the result of Ness. The method of Wasserburg *et al.*[9] and of MacDonald[10] for the Earth based on equation (2) yields abundances far lower than correspond to common surface rocks like basalt.

A similar situation seems to prevail for the Moon[20]. Mean abundances of U and Th in the lunar surface are $5 \cdot 4 \times 10^{-7}$ and $2 \cdot 2 \times 10^{-6}$ g/g, respectively—considerably higher than those appearing in Table 1 and within the range for a terrestrial basalt. The value 4·1 of Th/U is close to the terrestrial Wasserburg ratio, but the lunar ratio K/U is about 3×10^3, roughly one-third the terrestrial value. If lunar Wasserburg ratios show the same constancy as terrestrial ones, they require lowering of potassium abundance relative to the model considered here.

The present results make it abundantly clear that a relatively cold thermal regime in the Moon over roughly the last 3·5 Gyr can be justified consistently with observed levels of radioactivity in terrestrial rocks, without resort to the drastic suggestion by Anderson and Phinney[7] of Moon formation antedating that of the Earth by several milliard years. The mascon data seem to require a relatively hot Moon initially, contrary to Urey's idea of a Moon cold at origin[4].

Apollo 13 or 14 is scheduled to measure the heat flow J of the Moon, as predicted by Table 2.

I thank B. W. Augenstein, S. H. Dole, and Professors D. L. Anderson and D. T. Griggs.

Silicon Tetrahedral Sheet in Stilpnomelane

A CONTINUOUS hexagonal sheet of silicon tetrahedra (as in kaolinite) has lateral dimensions too small to permit articulation with a trioctahedral sheet in which the octahedral cations are larger than those of magnesium. In micas and chlorites where iron may occur in the octahedral sheet, the tetrahedral sheet is expanded by the substitution of aluminium for silicon; in astrophyllite[1] insertion of TiO_6 octahedra in the tetrahedra sheet permits coordination to the iron-bearing octahedral sheet. Expansion by inversion of tetrahedra has been found in the iron silicate zussmanite[2]. Stilpnomelane is a trioctahedral layer silicate with a layer thickness of about 12 Å. The octahedral cations are largely iron, which can range in oxidation state from all ferrous to almost all ferric[3], whereas the tetrahedral cations are nearly all silicon. In this paper the tetrahedral sheet of stilpnomelane is described.

The stilpnomelane used in this study is from Crystal Falls, Minnesota. Details of this sample and of the subcell structure of stilpnomelane have previously been described[4]. The unit cell of stilpnomelane is made up of sixteen subcells, and is triclinic with dimensions

$$a=21\cdot7\ \text{Å},\ b=21\cdot7\ \text{Å},\ c=17\cdot7\ \text{Å},\ \alpha=124°,\ \beta=96°,\ \gamma=120°$$

The X-ray reflexions that distinguish the unit cell from the subcell (so-called superlattice reflexions) are weak and are somewhat streaked parallel to c^*, indicating stacking disorder of the stilpnomelane layers. The superlattice reflexions are trigonally pseudosymmetric, and this property has been used to derive the Fourier transform of a single tetrahedral sheet. A distinction between the transform of the tetrahedral sheet and of the whole crystal is possible because only the tetrahedral sheet contributes to the superlattice reflexions.

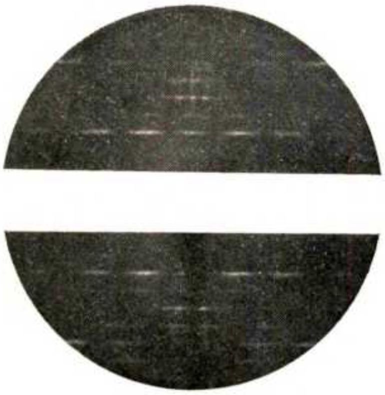

Fig. 1. Precession photograph of stilpnomelane, $h0l$, $0kl$, $\bar{h}hl$ triple exposure, superlattice reflexions only. Rows are parallel to c^*.

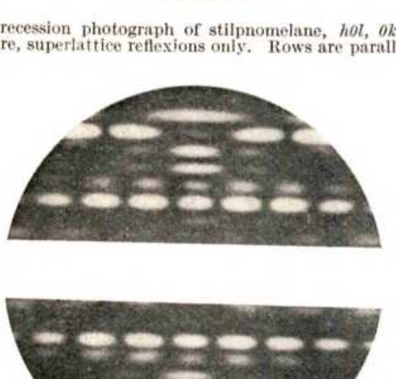

Fig. 2. Optical diffraction pattern (above) produced from the mask (below).

The tetrahedral sheet has three-fold symmetry about c^* but the triclinic reciprocal lattice does not. Superposition of reciprocal lattice planes spaced at 120° around c^* thus triples the number of points at which the Fourier transform can be observed and shows the transform of a single tetrahedral sheet[5]. The structure of the tetrahedral sheet was deduced by simulating the X-ray diffraction pattern (shown in Fig. 1) using an optical diffractometer[6] illuminated with an He–Ne laser (Fig. 2).

Based on this tetrahedral arrangement the full unit cell contains 48 octahedral cations, 72 tetrahedral cations, and 216 anions, and may be written

$$[(\mathrm{Al},\mathrm{Fe}^{+3})_x(\mathrm{Fe}^{+2},\mathrm{Mg},\mathrm{Mn})_{48-x}(\mathrm{OH})_{48-x}\mathrm{O}_{48+x}]$$
$$[\mathrm{Si}_{30\text{ to }36}\,\mathrm{Al}_{6\text{ to }0}\,\mathrm{O}_{60}]_2$$

Chemical analyses in the literature[3] show that up to five alkali atoms may be incorporated in the structure, as well as a considerable quantity of water.

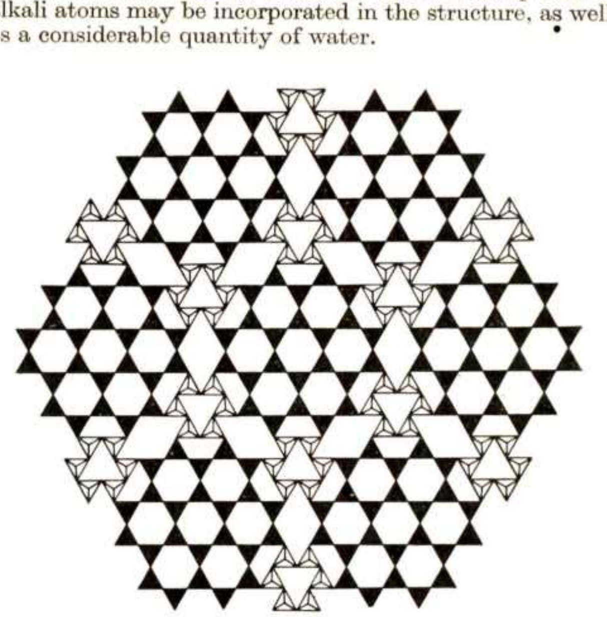

Fig. 3. Plan view of the stilpnomelane tetrahedral sheet. Black triangles represent tetrahedra coordinated to the octahedra; outline tetrahedra coordinate at their apices to a like sheet above.

The diagram of the tetrahedral sheet (Fig. 3) shows that articulation of tetrahedra to octahedra is only achieved over a short distance, producing "islands" of 24 tetrahedra linked by trigonal rings of six tetrahedra. Each tetrahedron of the trigonal ring is joined by its apical oxygen to a like but inverted ring above, which in turn serves to link further "islands" of tetrahedra connected to the next octahedral sheet. The tetrahedral sheet figured is that of a ferri-stilpnomelane. The larger octahedral sheet of ferro-stilpnomelane ($a=22\cdot0$ Å) can easily be accommodated by expanding the trigonal rings of tetrahedra to a more nearly hexagonal shape. There is ample space between the "islands" of tetrahedra and within the paired trigonal rings of tetrahedra to accommodate the alkali atoms and water recorded in most analyses of stilpnomelane.

Crystalline Structures of Alginic Acids

WE have recently obtained X-ray diffraction photographs from orientated samples of alginic acid preparations in which the ratio of mannuronic acid to guluronic acid was known. The purified unorientated material was supplied by Dr A. Haug, and our results form the basis for structure determinations of polymannuronic acid and polyguluronic acid respectively.

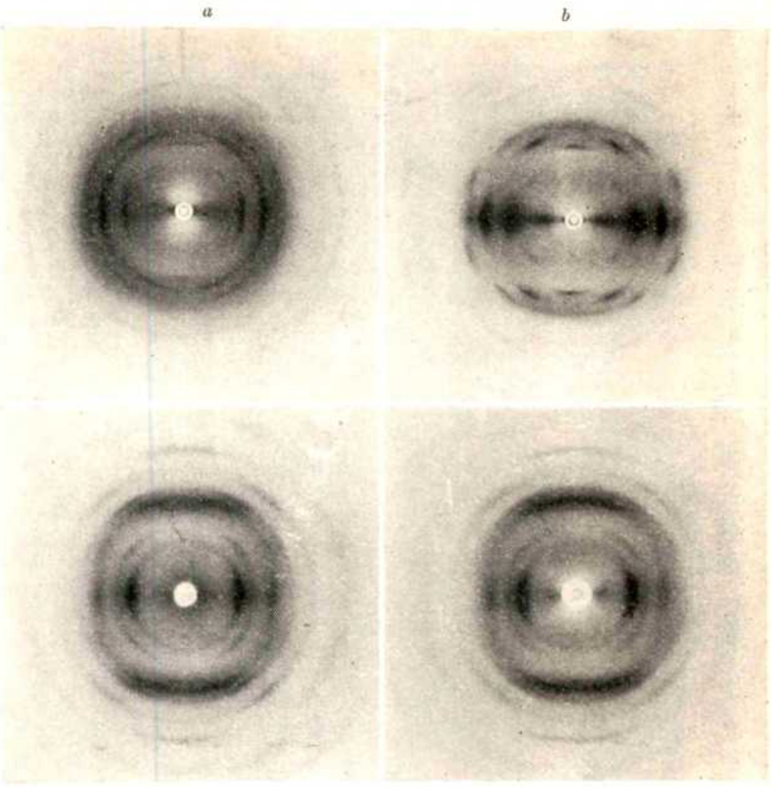

Fig. 1. X-ray fibre diffraction photographs of alginic acids. *a*, 96 per cent mannuronic acid; *b*, specimen isolated from *Fucus serratus*; *c*, commercial alginic acid; *d*, 73 per cent guluronic acid.

The discovery that alginic acid preparations of different composition could give rise to different X-ray powder photographs was made originally by Frei and Preston[1]. Although they recognized that the analyses of their alginic acids had to be interpreted with caution, they nevertheless concluded then that there were two types of X-ray powder photograph and they correlated these with polymannuronic acid and polyguluronic acid.

Fig. 1*a* shows the X-ray fibre diffraction photograph obtained from a sample of alginic acid consisting of 96 per cent mannuronic acid. To our knowledge this is the first authentic standard for polymannuronic acid. Fig. 1*b* is the X-ray fibre diffraction photograph of a specimen of alginic acid isolated by us from the brown alga, *Fucus serratus*. This is clearly the same X-ray fibre diagram as Fig. 1*a* and therefore must refer to polymannuronic acid. Fig. 1*c* shows the "usual" alginic acid X-ray fibre diagram as obtained by Astbury[2] in the 1940s from samples of commercial alginic acid and supposed, by him, to refer to polymannuronic acid. Fig. 1*d* shows the X-ray fibre diffraction photograph we have obtained from a sample of alginic acid containing 73 per cent guluronic acid and 27 per cent mannuronic acid. (This sample was the richest in guluronic acid from which orientated specimens could be prepared.) This latter substance gave the same X-ray powder diagram (see Fig. 2) as a degraded[3] sample of alginic acid containing 92 per cent guluronic acid. It therefore appears that the mannuronic acid units in the 73 per cent guluronic acid sample do not contribute to the X-ray diffraction pattern (as suggested previously[1]). We therefore conclude that the X-ray fibre diagram shown in Figs. 1*c* and 1*d* is indeed that of polyguluronic acid.

We are able to give the following preliminary details of the structures of these two substances.

Polymannuronic acid: The X-ray fibre diffraction photograph (Fig. 1*b*) has been indexed to an orthorhombic unit cell in which $a = 7{\cdot}58$ Å, $b = 10{\cdot}35$ Å (fibre axis) and $c = 8{\cdot}58$ Å, the unit cell containing two disaccharide chain segments with probable space group $P2_12_12_1$. Chemical evidence indicates that the D-mannuronic acid units are β-1→4 linked, and it is therefore satisfying that the fibre repeating distance of 10·35 Å is the same as that observed in the three other β-1→4 linked hexosans, cellulose chitin and mannan[4,5]. In models of these substances, the required repeating distance can be obtained by constructing chains in which the monosaccharide units are in the energetically favourable C1 chair conformation, while simultaneously maintaining an *intra* residue hydrogen bond between the $—O_3H$ and the ring oxygen atom (O_5) of the next sugar unit in the chain (that is, $O_3 \ldots O_5$ distance of 2·7–2·8 Å). A chain built in this way automatically contains di-equatorially (1e, 4e) (ref. 6) linked sugar units (without regard to the nature of the sugar units itself). This is the basic structural form which we have adopted in model building studies of polymannuronic acid.

Polyguluronic acid. The X-ray fibre diffraction photograph of this substance (Fig. 1*d*) has been indexed to an orthorhombic unit cell also containing two disaccharide chain segments and in which $a = 8{\cdot}6$ Å, $b = 8{\cdot}72$ Å (fibre axis) and $c = 10{\cdot}74$ Å with probable space group $P2_12_12_1$ (see also ref. 2). The most significant difference from the polymannuronic acid structure is the fibre repeat of 8·72 Å. This value can be obtained in molecular models by maintaining the 1→4 linked L-guluronic acid units in the *1C* conformation[7], the glycosidic linkages having the α-configuration. Thus the building units are di-axially (1*a*,4*a*) linked. When the sugar units are arranged in this way, it is found that several possibilities exist for the formation of *intra* residue hydrogen bonds between the equatorial hydroxyl group of the C_2 atom $(—O_2H)$ and either oxygen atom in the carboxyl group of the adjacent sugar unit in the chain. It is likely that other examples of 1*a*,4*a* linked structures exist. For example, poorly orientated fibre diffraction photographs of pectic acid (α-1→4 linked poly D-galacturonic acid) show the same fibre repeating distance of 8·7 Å (see also refs. 2 and 8), and this can be understood if the D-galacturonic acid units are in the *C*1 conformation.

Attention is currently being directed to the arrangement of the chains of polymannuronic and polyguluronic acid in the unit cells and the nature and extent of inter-chain bondings. Trial structure factors have been calculated and refinement of the models is in progress.

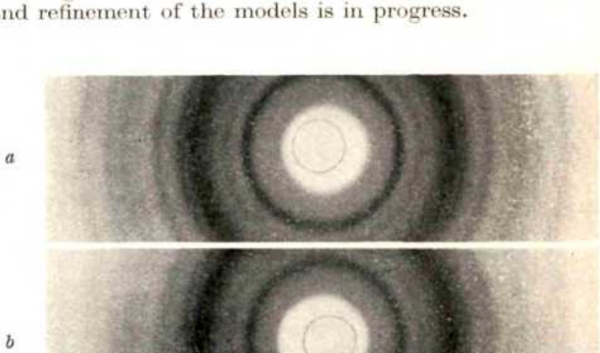

Fig. 2. X-ray powder photographs of (*a*) 92 per cent guluronic acid and (*b*) 73 per cent guluronic acid.

It is expected that the structural determinations of these substances will provide information which will be helpful in reaching an understanding of the physical and biological properties of these molecules.

We thank Professor R. D. Preston and Dr Eva Frei for useful discussions and Dr K. M. Rudall for providing the photograph in Fig. 1*c*. One of us (E. E. S.) acknowledges an award from the International Atomic Energy Agency.

Stored Energy in Creep Deformed Graphite

Graphite which has been strained in tensile creep releases a very large amount of stored energy when the creep stress is reduced, as happens in the dip test[1]. The very large amount of negative creep (actual shrinkage of the specimen while it is still under an appreciable applied tensile force) that takes place after a stress reduction is shown graphically in Fig. 1. Three individual stress reduction tests are shown. The work the specimen does against gravity in lifting the hanging weights is measured by the distance the specimen shrinks in negative creep multiplied by the remaining applied force. In a series of tests on ZTA graphite, the largest measured amount of energy released was $1{\cdot}1\times10^6$ ergs/cm^3 (0·17 calories/g atom). This was released when one specimen was strained almost to fracture (20 per cent elongation) at 3,200 pounds inch^{-2}, at which point the applied stress was reduced to 1,600 pounds inch^{-2}. The negative creep strain after the load reduction was 1·2 per cent. In time the negative creep period ended, but additional negative creep, some four times greater than that already measured, then occurred after complete removal of the applied stress. If the total energy release were proportional to that measured after the initial stress reduction, it would have been about $5{\cdot}5\times10^6$ ergs/cm^3. It was probably less than this. For further calculations, however, let us assume that the released energy was somewhere between $1{\cdot}1\times10^6$ and $5{\cdot}5\times10^6$ ergs/cm^3.

The total work done on the sample per unit volume during creep was simply the product of the creep stress and the creep strain. Dividing this into the energy recovered puts the recoverable percentage of the total expended energy at between 3 and 15 per cent.

We now compute from the appropriate surface and line energies the crack area or dislocation line length per unit volume which, if annihilated during recovery, would release $1{\cdot}1\times10^6$ to $5{\cdot}5\times10^6$ ergs/cm^3.

The energy per unit area for a basal plane cleavage crack is about 150 ergs per cm^2, according to theory[2,3]. The average crack opened up during creep is coin shaped and is approximately 0·01 cm in diameter[4]. Such a crack, if it is smooth, has a surface area of $1{\cdot}6\times10^{-4}$ cm^2. The number of such cracks per cm^3 necessary to release the required energy on their annihilation is between $0{\cdot}7\times10^{10}$ and 3×10^{10}; their spacing, if arranged in a rectangular grid, is between 0·003 and 0·005 cm.

The line energy per unit length, Γ, of a dislocation is

$$\Gamma = \frac{kb^2 \ln (\overline{R}/R_0)}{4\pi} \tag{1}$$

and in graphite is $1{\cdot}1\times10^{-4}$ ergs per cm length (here b is the Burgers vector, 2·46 Å; $\overline{R}$ the dislocation spacing, about 1000 Å; R_0 the core diameter, 1 Å; and k an elastic constant term, 4×10^{11} dynes per cm^2). The method of Hirth and Lothe[5] was used to compute k. Their equations (13–84 and 13–137) show that for anisotropic elastic media k, the so-called energy factor, must replace G, the shear modulus, which is normally used in equations to calculate line energy. If this modification for the anisotropic elastic behaviour of graphite is not made and the interlayer shear constant is used instead, Γ is two orders of magnitude smaller. An unacceptably great length of annihilating dislocation results. Annihilation of 1×10^{10} to 5×10^{10} cm per cm^3 length of dislocation would account for the observed release of stored energy.

From these calculations, either form of imperfection could account for the observed energy release because the calculated crack and dislocation densities do not seem unrealistically large. Almost all of the elongation observed in tensile creep of graphite has been shown[4] to be associated with the opening of cracks. With the layered structure of graphite, however, the opening of a crack must involve not only forming new surface but also bending the surrounding material, in which dislocations are certainly involved. Either surface area or bending deformation could dominate in the storage of energy, and at present it is not possible to favour one mechanism over the other. Perhaps transmission electron microscopy of the dislocation structure and crack surface area measurement (by the B.E.T. gas adsorption method, for example) could be used to determine whether either imperfection density changes during recovery in the required way.

Very little quantitative information has been published on the amount of energy stored in materials deformed by creep, but it seems likely that most materials would not store as much as does graphite. In a metal with many slip systems, all grains in a polycrystalline sample can find suitable slip systems. As a result, all grains deform once the flow stress is reached. But there are not enough active slip systems in the hexagonal structure of highly anisotropic graphite. Graphite can therefore sustain higher stresses than a metal and can thereby store more energy. The amount of recoverable energy, between 3 and 15 per cent of the work done on the graphite sample

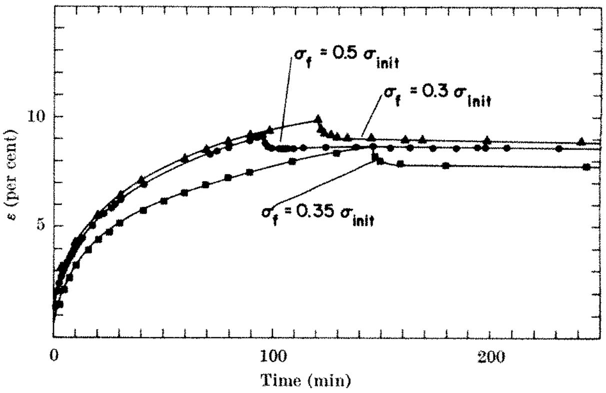

Fig. 1. Creep tests at 2,500° C on ZTA graphite in which the initial stresses were 3,200 pounds inch^{-2} and the final stresses were at the indicated values. Note the negative creep period that follows the stress drops; the sample does work against gravity by lifting the weights hung on the sample. The energy released per unit volume is the product of the final stress and the negative creep strain.

during creep, is comparable with that reported for cold worked metals, but the structures of creep-deformed metals do not contain the large density of dislocations normally associated with metals in the cold-worked state. The fact that graphite lacks slip systems capable of plastically deforming any given crystal along the *c*-axis must, in some way, be responsible for the large build-up of stored energy.

This work was carried out under the auspices of the US Atomic Energy Commission and with the support of the US National Aeronautics and Space Administration. We thank Dr R. B. Gibney and Mr M. C. Smith, under whose leadership this work was performed, and Mr J. J. Medina for assistance in the laboratory.

Catalytic Oxidation of SO_2 on Carbon Films studied by Electrical Resistance Measurements

ELECTRICAL resistance measurements have been used for investigating the mechanism of chemisorption and catalysis on metals and oxides, but comparable data for carbon are scarce. We have demonstrated[1] that the resistance of vacuum evaporated carbon films increases during oxygen chemisorption. We have also used this technique, which rapidly provides information on chemisorption by carbon, to study the kinetics and energetics of oxygen chemisorption[1].

We have now measured the effect of various adsorbates on the resistance of carbon films. Particularly striking effects were observed with (SO_2+O_2) mixtures and we report here some results for this system. The experimental details have been described[1]. Films were transferred in air to the resistance-measurement apparatus, where vacuum heat treatments and gas admission were carried out in the absence of air. The resistance of evaporated carbon films decreases[1-4] on vacuum heat treatment with an annealing process which has an activation energy increasing from 20 to 90 kcalories/mole[5,6], according to the extent of annealing. Heat treatment also removes surface oxygen, and room temperature resistance is sensitive to oxygen only for heat treatment temperatures above about 200° C (ref. 1). The present experiments involved room temperature measurements on films initially heat treated for 6 h under vacuum at 350° C.

Admission of SO_2 decreased film resistance, typically by 5 per cent for pressures of 20 mm Hg. The decrease was completed within 2 s and was rapidly reversed by evacuation at room temperature. All heat treated films, not previously exposed to SO_2, showed the usual increases in resistance under O_2 and these were completely reversed by evacuation only at the temperature of the initial heat treatment[1].

The effect of (SO_2+O_2) mixtures was strikingly different from the effects of each gas alone. Such mixtures caused large decreases in resistance and these were not reversed at all by evacuation at room temperature. It took about one thousand minutes to attain essentially constant resistance under (SO_2+O_2), but a large fraction of the change took place within a few minutes (Fig. 1). The overall decrease amounted in some cases to over 70 per cent. Evacuation at higher temperatures caused a progressive reversal which was complete at 200°–250° C (Fig. 1). Both the rate and extent of the decreases in resistance increased with the partial pressure of each gas (Figs. 2 and 3). It is remarkable that O_2 partial pressures below 10^{-1} mm Hg produced significant irreversible decreases; in the absence of SO_2 the resistance increases brought about by O_2 took place only at pressures above several mm. The decreases in resistance, brought about by (SO_2+O_2), followed Elovich kinetics[1,7-9] during the later stages of the process. The initial kinetics may be complicated by a contribution from the rapid reversible effect of SO_2 alone, but it is interesting that none of the (SO_2+O_2) effects are reversed by evacuation at room temperature.

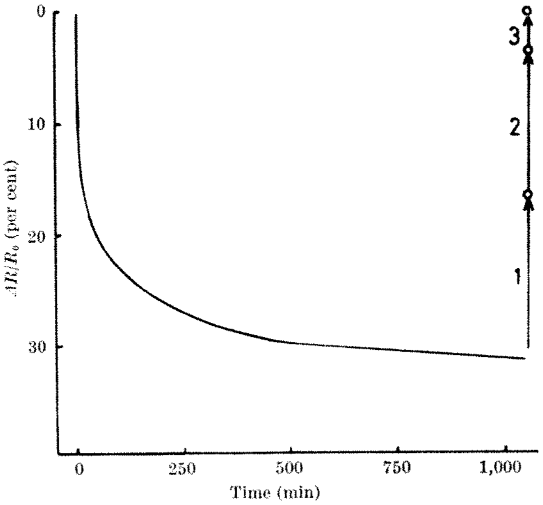

Fig. 1. Percentage decrease in resistance ($\Delta R/R_0$ per cent) with time following admission of an (SO_2+O_2) mixture (16 mm SO_2 and 25·5 mm O_2) to a film heat treated at 350° C. $R_0=1{\cdot}62\times10^7\,\Omega$. Also shown is the reversibility of the effect on evacuation to constant resistance at temperatures up to 230° C. 1, Evacuation at 100° C; 2, evacuation at 200° C; 3, evacuation at 230° C.

Reversal of the (SO_2+O_2) effect could also be achieved by evacuation at room temperature (half an hour),

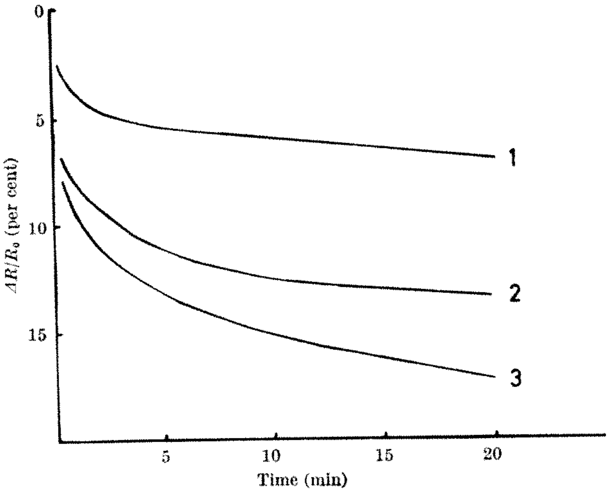

Fig. 2. Resistance decreases under (SO_2+O_2) at an SO_2 partial pressure of 16 mm and varying O_2 partial pressures. Original resistance ($1{\cdot}57\times10^7$ Ω) recovered between each experiment by 1 h evacuation at 300° C. Film previously heat treated at 350° C. Curve 1, $8{\cdot}5\times10^{-2}$ mm O_2; decrease after 1,000 min 14·1 per cent. Curve 2, 1·5 mm O_2; decrease after 1,000 min 21·2 per cent. Curve 3, 6·0 mm O_2; decrease after 1,000 min 31·6 per cent.

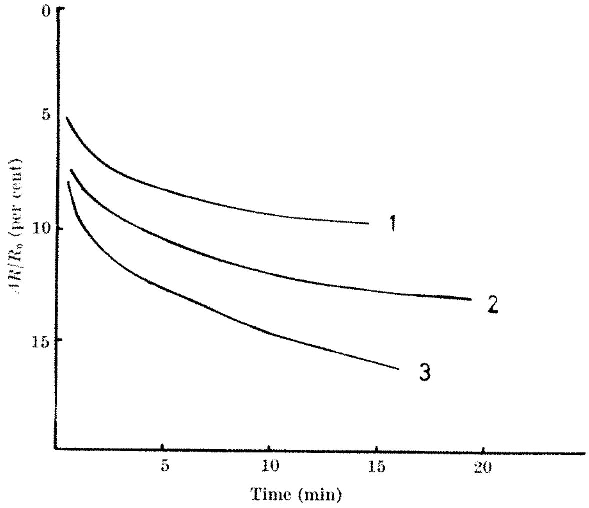

Fig. 3. Resistance decreases under (SO_2+O_2) at an O_2 partial pressure of 16 mm and varying SO_2 partial pressures, for the film of Fig. 2. Original resistance recovered between each experiment by 1 h evacuation at 300° C. Curve 1, 1·0 mm SO_2; decrease after 1,000 min 12·7 per cent. Curve 2, 5·0 mm SO_2; decrease after 1,000 min 20·4 per cent. Curve 3, 16·0 mm SO_2; decrease after 1,000 min 34·6 per cent.

followed by exposure to water vapour (3–15 mm Hg) at room temperature. The resistance increased when water vapour was admitted, and after several hours a constant value corresponding to a complete reversal of the (SO_2+O_2) effect was attained. No further resistance changes took place on subsequent evacuation at room temperature. Alternate treatments with (SO_2+O_2) and water vapour could be carried out indefinitely with identical cycles of resistance changes. Resistance increases were observed on admission of water vapour to films before treatment with (SO_2+O_2) but these were small (< 5 per cent) and were partly reversed by room temperature evacuation (compare with ref. 1). When water vapour was present in (SO_2+O_2) mixtures, their effect on resistance was largely inhibited.

Conventional measurements have shown[10–15] that SO_2 chemisorption on carbons is enhanced by the presence of O_2 in the gas phase. Weakly chemisorbed O_2 is believed[11,12] to react with adsorbed SO_2 to produce surface (SO_3). Our results confirm the promotion of SO_2 chemisorption by O_2. We assume that $(SO_3)_{ads}$ is responsible for the resistance decreases which are reversed by evacuation at 200°–250° C. It is relevant that desorption of SO_3 from sugar chars is virtually complete at 250° C (ref. 16).

The resistance technique can provide direct evidence about the form of chemisorbed species (see references in ref. 1). The large changes in resistance, observed under (SO_2+O_2), suggest that formation of surface SO_3 involves charge transfer between the carbon surface and the adsorbed complex. This will involve electron transfer from carbon to $(SO_3)_{ads}$. Possible negatively charged forms of the adsorbed complex include either the sulphite ion $(SO_3)^{2-}$ or $(R{-}SO_3)^-$, an anion analogous to that of a sulphonic acid $(R{-}SO_3)^-$. Carbon films consist[2,17,18] of graphitic regions some 10 Å in diameter separated by tetrahedrally bonded carbon. The structure involving $(R{-}SO_3)^-$ could represent an SO_3 group covalently bonded to a graphitic region (R) to form a macro anion, with an adjacent region acting as the electron donor and forming a macro cation. Decreases in resistance could result from an increase in the number of positive charges responsible for conduction. Thermoelectric[3] and field effect[19] data indicate that conduction in these films does involve positive carriers. Alternatively, charged chemisorbed species may alter resistance by affecting carrier mobility through modification of potential barriers between surface regions[4].

A more pronounced enhancement of SO_2 chemisorption occurs[12–15] in the presence of both O_2 and water vapour; adsorbed H_2SO_4 is formed in these conditions. Our results on the inhibition of the (SO_2+O_2) effect by water vapour may result from the reaction—

$$SO_{3ads}+H_2O \longrightarrow H_2SO_{4ads}$$

if resistance is decreased by SO_{3ads} but not by H_2SO_{4ads}. The formation of H_2SO_4 from negatively charged $(SO_3)_{ads}$ and H_2O would return the charge on the $(SO_3)_{ads}$ to the carbon. The repetitive cycling experiments, involving alternate treatment with (SO_2+O_2) and water vapour, suggest that H_2SO_4 vacates the sites at which it is formed from $(SO_3)_{ads}$, making them available for further reaction between SO_2 and O_2.

Large decreases in resistance were observed only when both SO_2 and O_2 were present in the gas phase. This suggests the presence of a reactive, weakly adsorbed intermediate in equilibrium with molecules in the gas phase. Likely candidates for such an intermediate are the adsorbed SO_2 which reversibly decreases resistance, or the types of weakly chemisorbed O_2 which reversibly decrease[5] or increase (our unpublished work) the spin concentration of carbon films.

We are further investigating these resistance effects. Radioactively labelled SO_2 is being used to correlate the number of chemisorbed SO_2 molecules with the resistance changes.

Iodine as a Boundary Lubricant: A Contrary View

Roberts and Owens reported[1] that charge-transfer complexes of iodine and *n*-butylbenzene were effective boundary lubricants for titanium sliding on titanium. The discovery is interesting because titanium and its alloys are being used more widely and are difficult to machine and lubricate.

According to Roberts and Owens[2], charge–transfer complexes of iodine and aromatic compounds greatly reduce friction and wear with titanium or steel sliding on titanium. Similar results were obtained with a mixture of these complexes and a straight-chain hydrocarbon oil. The suggested lubrication mechanism was the formation of the low shear strength laminar solid TiI_2 at the wearing interface; the hydrophobic nature of the lubricant was believed to prevent the titanium diiodide from reacting with water in the air. The idea is attractive, and indeed G. W. Rowe had shown earlier (see description in ref. 3) that the exposure of clean titanium to iodine vapour resulted in lower friction and the formation of TiI_2.

Roberts and Owens have also reported that iodine–anisole complexes are effective for the boundary lubrication of chrome steel[4]. They suggested that the mechanism may be the same as that for the lubrication of titanium, because FeI_2 is a lamellar solid with the CdI_2 structure.

The results of friction, wear and metalworking tests confirm that the iodine-containing fluids are effective as boundary lubricants. These findings and the diiodide layer-lattice mechanism have been widely publicized[5-8]. But I find the data in support of this theory far from convincing. For example, each of the metals studied by Roberts and Owens (titanium, steel and chrome steel) is capable of forming a diiodide (TiI_2, FeI_2 and even CrI_2). What about substances that do not form diiodides ?

I here summarize findings almost completely at odds with Roberts and Owens's theory.

(1) The formation of a diiodide layer is not essential for an antifriction or antiwear effect of iodine as a lubricant additive. (2) The iodine need not be in the form of a charge–transfer complex with an aromatic compound in order to function. (3) The mechanism, although not fully understood, is apparently simpler and does not depend greatly on the characteristics of the rubbing solids. (4) One of the most striking effects of iodine is its action in producing extremely low friction, particularly in steel systems.

I first discovered that minor amounts of elemental iodine in hydrocarbons such as mineral oils are unusually effective in reducing friction with steel-on-steel[9,10]. The primary system was one of pure sliding and relatively high contact stress—a ball-on-cylinder device described in ref. 11. As little as 0·0075 per cent iodine, in either solvated or diatomic form in a mineral oil, reduced friction in this system by well over 90 per cent. Coefficients of friction were reduced from the usual value of about 0·1 to the unusually small value of 0·01; in several cases, to values as low as 0·001. Furthermore, the extent of metallic contact was greatly reduced. Conventional lubricant additives (such as fatty acids, phosphates and halogen compounds) usually reduce friction by no more than 20 to 30 per cent in these conditions. In a few cases, friction reductions of 50 per cent have been observed with ~1 per cent additive; but the large effect of such a low concentration of additive had never been observed. Iodine was much more effective than other halogens, even though FeI_2, $FeBr_2$ and $FeCl_2$ all have layer structures.

Similar effects occurred in other steel systems, including engine friction, gear scoring, and conventional extreme pressure tests. In the high-load gear and extreme pressure tests I believe that the iodine, rather than acting as a classical antiweld agent, may have prevented scuffing by keeping the surface temperatures low through a great reduction in friction.

Solutions of iodine in pure aliphatic hydrocarbons (such as hexadecane) were equally effective; thus aromatic compounds, and therefore charge–transfer complexes, need not be present.

If the layer-lattice theory is correct, iodine should not work with aluminium because the reaction product, AlI_3, is a three-dimensional, non-layer complex. Furthermore, iodine would not be effective with substrates such as gold, glass or polymers, for they do not readily react with iodine and, even if they did, would not be expected to yield layer-lattice structures. For example, although gold does not easily react with iodine, the compounds AuI and AuI_3 do exist; but neither has a layer structure. I therefore studied the action of iodine with other rubbing solids, using the same ball-on-cylinder device.

With aluminium-on-aluminium, the addition of minor amounts (such as 0·075 per cent) of iodine to a white mineral oil usually produced a marked decrease in friction and wear, particularly at higher loads. For example, at a load of 4,000 g, iodine reduced the coefficient of friction from about 0·12 to 0·04 and the wear scar diameter by about 40 per cent.

With gold-on-gold, iodine usually reduced friction by about 85–90 per cent; at greater loads, it increased wear by approximately 15 per cent. But the increase in wear was not responsible for the lower friction through a polishing or geometry effect.

With glass-on-glass, iodine reduced friction by a factor of about three. Furthermore, there was an enormous reduction in wear (see Table 1).

Table 1. INFLUENCE OF I_2 ON FRICTION AND WEAR WITH GLASS-ON-GLASS : BALL-ON-CYLINDER TESTS, 16 MIN AT 120 R.P.M.

Load (g)	I_2 in white oil (per cent)	Coefficient of friction	Wear scar diameter (mm)
30	0	0·060	0·79
	0·75	0·020	0·0*
60	0	0·042	1·08
	0·75	0·015	0·0*
240	0	0·125	2·05
	0·75	0·046	0·0*

* No wear could be detected at × 20 magnification.

I also observed that iodine leads to the formation of an unusual pattern of deposits, consisting of many small dark droplets near the contact region on a ball; the pattern resembles lines of force in an electric or magnetic field. The chemical composition of the droplets has not been determined, but the resinous nature of the deposit may mean that the hydrocarbon is also involved in some way with the film-forming process. Iodine is well known as an effective catalyst for a variety of chemical reactions. One possibility, unproven, is that a gross protective polymeric substance or viscous film is formed in the contact zone.

Sliding contact tests have also been carried out with a polymer-on-polymer (polymethylmethacrylate) system. The effect was basically the same: minor amounts of iodine dissolved in a white oil markedly reduced both friction and wear.

The action of iodine thus seems not to be simply that of a classical halogen-containing extreme-pressure additive. (Most people think that these rather complex organic EP compounds function by decomposing and reacting with rubbing metal surfaces at high temperatures to form metal halides, not necessarily of the layer-lattice type.) The data obtained with elemental iodine dissolved in a hydrocarbon suggest that a less specific and possibly simpler lubrication mechanism may exist. For example, the adsorption of the rather large iodine molecule from an organic solution could conceivably lead to a significant repulsive force between the solids. I am now studying this idea and trying to elucidate the mechanism by which iodine functions as a boundary lubricant.

Charge Transfer Complexes of Tropylium and *N*-Heterocyclic Cations with Aromatic Amines

THE tropylium[1-3] and *N*-heterocyclic cations[4-6] have been shown to act as electron acceptors in forming complexes of the electron–donor–acceptor type with halide ions and aromatic hydrocarbons as donors. Aliphatic amines form adducts of the σ-complex type with *N*-heterocyclic cations[7].

Addition of an aromatic amine to a solution of tropylium fluoroborate, *N*-methylquinolinium or *N*-methylacridinium perchlorate led to the observation of a new, featureless absorption band in the visible. With *p*-phenylenediamine and *p*-toluidine, this band appeared only transitorily, decaying too rapidly for establishment of its position, while *NNN*¹*N*¹-tetramethyl-*p*-phenylenediamine gave immediately the characteristic absorption and electron spin resonance spectrum of Wurster's blue radical cation. Other amines gave rise to more stable absorption bands, the positions of these being given in Table 1. Plotting $\bar{\nu}_{\max}$ for these bands against the ionization potential of the donor for both amine and aromatic hydrocarbon complexes of the tropylium ion and against $\bar{\nu}_{CT}$, the charge transfer (CT) band maximum for complexes of chloranil with the same amines gave good linearity in both plots, thus establishing the CT nature of the transition and the complexes as the electron–donor–acceptor type.

Table 1. CHARGE TRANSFER BAND MAXIMA (NM) FOR AROMATIC AMINE/CATION COMPLEXES

Acceptor Donor	Tropylium	*N*-methyl-quinolinium	*N*-methyl-acridinium
Aniline	520^a		
N-methylaniline	552^b	397^c	500^a (shoulder)
NN-dimethylaniline	571^b	408^d	$537{\cdot}5^a$
NN-diethylaniline	578^b	430^c	570^a
σ-toluidine	$533{\cdot}5^b$		500^a (shoulder)

a, In dichloromethane; *b*, in 50/50 dichloromethane/acetonitrile; *c*, in acetonitrile; *d*, in ethanol.

The CT bands decayed over a period of time, being less stable in solvents of high polarity, which is in agreement with the observation[8] that carbazole complexes of the tropylium ion are stable in methyl cyanide, the addition of methanol or water leading to formation of carbazole radical cations. Preliminary investigation showed that tropilidene is one of the major products of decomposition of the tropylium complexes. Tropylium is known to abstract hydrogen from tertiary aliphatic amines[9] and from methyltropilidene[10], to form tropilidene. The mechanism in these reactions is postulated as hydride transfer. Kosower[11], however, has suggested that where intermediate CT complex formation occurs, hydride transfer, that is, a two electron transfer process, might alternatively be interpreted as two one electron transfers, electron transfer being followed by hydrogen atom transfer. Observation of electron transfer between tropylium and *NNN*¹*N*¹-tetramethyl-*p*-phenylenediamine and the carbazoles to form the corresponding radical cations lends support to a mechanism for the decomposition of tropylium–amine complexes via the electron transferred form of the CT complex.

The strongest evidence for an electron transfer mechanism was found for complexes of *NN*-dimethylaniline (DMA) and *NN*-diethylaniline with the *N*-methylquinolinium ion. Decay of the CT band in these systems was accompanied by the growth of a characteristic spectrum with three bands in the 440–480 mμ region and three bands in the 900–1,100 nm region. This is identical with the spectrum reported[12] for *NNN*¹*N*¹-tetramethylbenzedine (TMB) radical cation. The growth of this spectrum was accompanied by the growth of an electron spin resonance absorption, both being identical to those obtained by bromine oxidation of TMB. DMA also yields TMB and its radical cation on anodic oxidation[13] and we believe that a similar mechanism is probably operative in the decomposition of the complex—that is, formation of DMA (or DEA) radical cation by electron transfer within the complex, followed by tail-to-tail coupling of the radical cation and elimination of two protons to give TMB. The radical cation of TMB is formed by further electron transfer to the acceptor.

$$\mathrm{PhNMe_2 + A^+ \rightarrow \underset{CT\ complex}{PhNMe_2.A^+} \rightarrow Ph\overset{+}{N}Me_2}$$

$$\mathrm{Ph\overset{+}{N}Me_2 \rightarrow Me_2NPhPhNMe_2 + 2H^+ \xrightarrow{A^+} TMB^+}$$

Decomposition of the tropylium complexes may occur by a slightly different route, hydrogen atom transfer from the *N*-alkyl group of the amine to the intermediate tropyl radical giving tropilidene. No electron spin resonance evidence was found for the intermediate arylamine radicals or for the tropyl radical, but this is in accord with the lack of electron spin resonance evidence for these intermediates in anodic oxidation or oxidative dimerization of aromatic amines[14]. We feel that the evidence, although of a preliminary nature, places these reactions in the group where a CT complex plays a definite part as intermediate in the chemical reactions.

Effects due to Non-equilibrium *p*H Conditions in the Radiolysis of Aqueous Systems

DURING studies of the pulse radiolysis of aqueous solutions of pyrimidines and related substances, we have observed the formation of short-lived organic species which are formed by reactions other than those of the free radicals H, OH and e^-_{aq} produced by the radiolysis of the solvent. On the basis of the evidence presented here, we believe that these molecular transient species are the result of acid-base reactions between the pyrimidines and the radiolytic yield of hydroxide ions. These processes, although unlikely to lead to permanent products, are important in the pulse technique where the correct interpretation of a transient absorption is vital.

Nitrous oxide saturated solutions of thymine (T) (10–600 μM) were irradiated with 0·1–2 μs pulses of electrons (2–4 MeV), typical doses being 1 krad/pulse. In these conditions, the primarily produced solvated electrons are converted to OH radicals according to $N_2O+e^-_{aq}\xrightarrow{H_2O}N_2+OH+OH^-$, thus effectively producing a one-radical system containing OH. The absorption spectrum of the OH adduct to thymine (represented as TOH) was studied between *p*H 5·5 and *p*H 7·5, usually in the presence of Sørensen phosphate buffer. The transient absorption in solutions at *p*H 5·5 (Fig. 1) decays by a second-order process, attributable to the reaction $2TOH\rightarrow$products. On increasing the *p*H of the solutions, however, an additional component became evident; it absorbed in the region 270–320 nm and decayed rapidly in an apparently first order process ($\tau_{\frac{1}{2}}\approx 3$ μs); the residual absorption then decayed by the second order process observed at lower *p*H. The initial decay appears as a "spike" on the oscillogram (Fig. 2). A plot of the absorption at 300 nm and at 400 nm as a function of *p*H is given in Fig. 3. No spike was observed in solutions of $pH > pK$ of the base (~ 10).

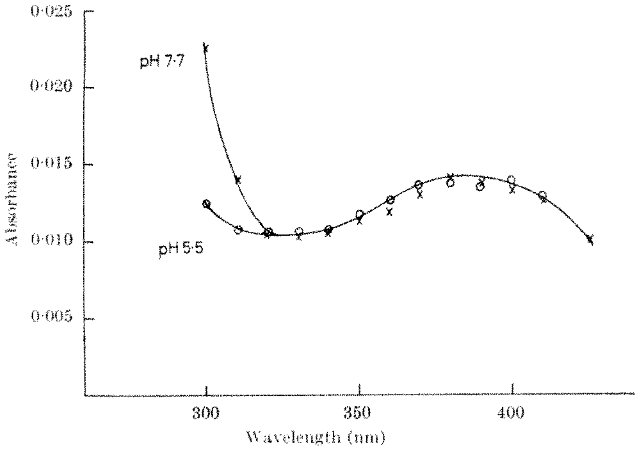

Fig. 1. Transient absorption spectra produced at *p*H 7·7 and 5·5 in 6×10^{-4} M thymine (N_2O saturated) with 4×10^{-3} M phosphate buffer by a 1·6 krad pulse of radiation.

A similar phenomenon was observed in uracil–N_2O solutions, but not in systems containing either thymidine, thymidylic acid, 1:3 dimethyl uracil, 1 methyl thymine or 2,4-dimethoxy uracil. Addition to thymine–N_2O solutions of excess of the OH radical scavenger diethyl ether, so that all the OH radicals reacted with the ether, resulted in a suppression of TOH (at 400 nm) but left the spike unaffected. It follows that the spike is not the result of OH radical reaction with the pyrimidine. Similarly, H atoms are not responsible because their rates of reaction with pyrimidines are at least one order of magnitude less than those of OH.

These experimental facts can be adequately accounted for by ionization of the pyrimidines on reaction with the radiolytically produced hydroxide ions. After a 0·2 μs pulse delivering a dose of 1·5 krad to a solution saturated with N_2O, the ion yields are: $[OH^-]=[H_3O^+]\simeq 5\times 10^{-6}$ M (ref. 1). The rate of reaction of the hydroxyl ion with pyrimidines is fast[2], for example, $k_{OH^-+\text{uracil}}=9{\cdot}9\times 10^9$ $M^{-1}\ s^{-1}$. In the competition (PyH = pyrimidine)

$$OH^-+PyH\rightarrow Py^-+H_2O \qquad (1)$$

$$OH^-+H_3O^+\rightarrow 2H_2O \qquad (2)$$

and given[3] that $k_2=1{\cdot}4\times 10^{11}\ M^{-1}\ s^{-1}$, therefore, it follows that a pyrimidine at a concentration of 10^{-4} M can compete equally with hydrogen ions for a hydroxyl ion. Re-establishment of the equilibrium will occur through the reverse of reaction (1); for uracil ($pK=9{\cdot}3$) this pseudo first-order process should have a half life of 3 μs. Thus if reaction (1) leads to a change in the spectral characteristics of the pyrimidine, the transient existence of P_y^- should be directly observable in the above pulse radiolysis experiments. Such spectral changes around 300 nm are known to occur in the ionization of thymine and uracil[4]; on the other hand, negligible changes occur with thymidine, thymidylic acid, 1 : 3 dimethyl uracil, 1 methyl thymine and 2,4-dimethoxy uracil. Assuming that the spikes in the irradiated thymine and uracil solutions are due solely to Py^-, then from known spectra[4] one can predict the spectral changes in the range 280–320 nm. Fig. 4 compares the predicted spectrum in the pulsed thymine solutions with the experimental points for the spectrum of the spike; the agreement is excellent.

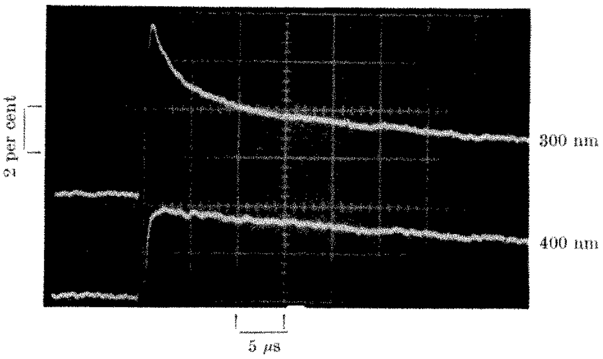

Fig. 2. Oscillograms of the transient absorption produced at *p*H 7 in 5×10^{-4} M thymine (N_2O saturated) by a 0·2 μs pulse of 2 krads. Upper trace at 300 nm showing the "spike"; lower trace at 400 nm.

In solutions containing phosphate buffer the following reactions of OH^- can also occur

$$OH^-+H_2PO^-{}_4\rightarrow HPO_4^{=}+H_2O \qquad (3)$$

$$OH^-+HPO_4^{--}\rightarrow PO_4^{\equiv}+H_2O \qquad (4)$$

Reaction (4) has a rate constant of $2\times 10^9\ M^{-1}\ s^{-1}$ (ref. 2). It is reasonable to assume that $k_3>k_4$, so that the observed suppression of the spike by phosphate buffer should be more marked at lower *p*Hs. This would explain the suppression of the spike on lowering the *p*H to 6·5 in the presence of 4×10^{-3} M phosphate buffer shown in Fig. 3.

The reaction of radiation-induced non-equilibrium quantities of hydroxyl ions with pyrimidines has been

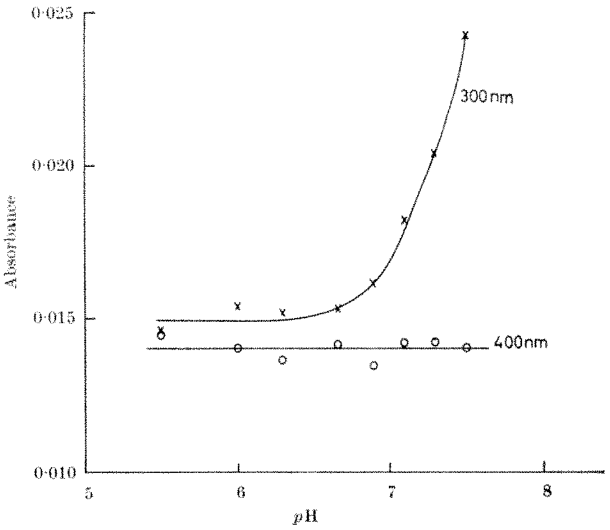

Fig. 3. Variation in transient absorption at 300 and 400 nm with *p*H. Solution irradiated as for Fig. 1.

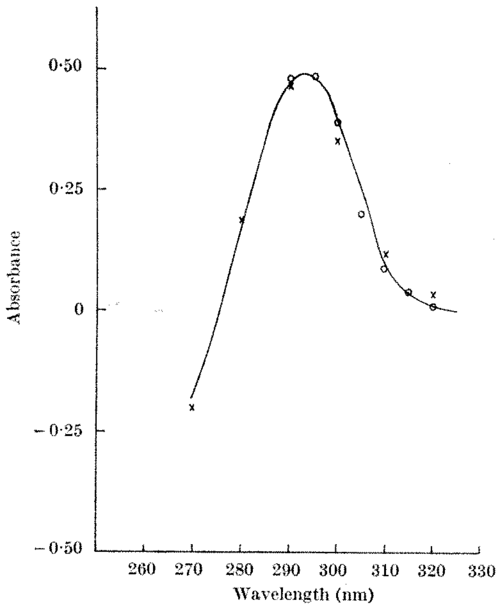

Fig. 4. Observed spectrum of the "spike" (experimental points) obtained in thymine solutions and the difference spectrum between equal quantities of thymine and its ionized form (solid curve). The curve was normalized to the experimental data at 290 nm.

clearly demonstrated. Such a phenomenon should be quite general and should occur wherever the ionization of an acid (or protonation of a base) occurs fast enough, and this will be observable spectrophotometrically where there are appreciable spectral differences between the conjugate acid and base forms of the solutes. Further, the possibility also exists for the occurrence of analogous reactions in non-aqueous systems.

Radiation Grafting of Polysulphides to Wool

Successful attempts to graft polysulphide polymers to wool have recently been made at this laboratory.

Interest in this kind of grafting was originally aroused by certain similarities in structure between the two—namely, disulphide bonds and, to a lesser extent, thiol terminal groups. It was hoped that a radiation-induced wool–polymer graft might show better mechanical properties than untreated wool. The mechanical properties we examined were load-extension and felting. Felting is the progressive fibre entanglement in wool resulting from mechanical agitation, particularly in the presence of water.

Polysulphide polymers are produced by reacting organic dihalides with sodium polysulphide[1-3]. The high molecular weight polysulphides formed can be converted to low molecular weight liquid polymers with thiol terminals by reductive cleavage of some of the disulphide bonds. The liquid product can be reconverted to rubbers of high molecular weight by a wide variety of methods.

The polysulphide polymers we used were manufactured by Thiokol Chemical Corporation of Trenton, New Jersey. The polymers chosen as representative of the range available were Thiokol LP-8 (ref. 4), Thiokol LP-33 (ref. 5) and Thiokol LP-32 (ref. 6), which have average molecular weights of 600, 1,000 and 4,000 respectively. These polymers are composed of 98 per cent (mole) dichloroethyl formal and 2 per cent (mole) trichloropropane. The finally cured product thus consists of long linear chains held together by the small amount of trifunctionality placed in the polymer by the trichloropropane.

Samples of 64s quality (denoting a mean fibre thickness of 20·6–22·0 µm) merino fleece and woollen cloth woven from 64s quality merino wool were irradiated with gamma rays from cobalt-60. The wool was immersed in a solution consisting of polymer, solvent and swelling agent during the irradiation. This is similar to the system of Stannett *et al.*[7] except that we used polymer instead of monomer. The concentrations were: polymer 3 to 5 per cent by volume; water, as swelling agent, up to 10 per cent by volume. Irradiations were carried out under nitrogen and in the presence of air at dose rates up to 100 krads/h. Solvents included dioxan, pyridine and dimethylsulphoxide, which dissolve the polymers and at the same time make it possible to add a certain amount of water before polymer is precipitated.

In each case it was found that the amount of polymer grafted to the wool was smaller when the irradiations were carried out under nitrogen than in the presence of air. With pyridine as solvent, no polymer at all was grafted under nitrogen. For absorbed doses of 20 to 30 Mrads and water concentrations of 10 per cent, maximum weight increases of 2 per cent and 12·7 per cent resulted for irradiations carried out under nitrogen and in air respectively.

Load-extension curves up to 30 per cent wet extension were obtained for untreated single fibres. Polymer was then grafted to these calibrated single fibres and the load-extension characteristics were re-examined. A steady decline in mechanical strength had taken place as the radiation dose and the grafted polymer had accumulated. Similarly calibrated fibres, however, irradiated in the same solvent–water solution but without polymer, showed a much sharper decline in mechanical strength, implying that the added polymer had contributed towards improving the mechanical strength or had partially protected the fibre from radiation damage. Thiols are effective protective agents in irradiations of chemical systems.

The felting tendency of the polymer grafted wool was greater than that of untreated wool, increasing with the radiation dose.

We found that the added polymer was chemically bonded to the treated wool, using Simpson's method[8]: the wool–polymer combination was reduced and alkylated[9], and then digested in pronase[10], a protease from *Streptomyces griseus*. If the polymer were chemically bonded to the wool, polymer with amino-acid residues attached would be likely to remain. Solvent extraction of this material and subsequent hydrolysis release some or all of these residues for amino-acid analysis. All radiation grafted samples so treated gave evidence of the presence of amino-acids in these hydrolysates, showing that there was chemical combination of polymer with the wool.

Piezoelectric Resonances in Amino-acids

CRYSTALS of amino-acids may exhibit the property of piezoelectricity[1-4] and, like other crystals, may belong to one of the twenty-one so-called piezoelectric crystalline classes[5]. Our particular interest in investigating piezoelectric resonances in amino-acids was in connexion with our current study of nuclear quadrupole resonances (NQR). For this purpose, it is preferable to choose non-piezoelectric amino-acids so that there is no interference in the detection of the quadrupole spectra[6,7].

The results of our measurements on amino-acids[8-11] are given in Table 1. Experiments are performed on powders, using a superregenerative spectrograph[12] of NQR type[13] specially adapted for this work[14]. We have studied principally the L isomers of amino-acids, the only ones occurring in proteins.

Table 1. COMPARISON OF EXPERIMENTAL AND THEORETICAL PIEZOELECTRICITY FOR AMINO-ACIDS

Amino-acid	Spatial group	Crystalline class	Theoretical piezo-electricity[16-19]	Experimental piezo-electricity
L-Alanine	$P2_12_12_1$	222	+	+

L-Proline	$P2_12_12_1$	222	+	+
DL-Proline				–
L-Serine				+
DL-Serine	$P2_1/a$	2/m	–	+
L-Threonine	$P2_12_12_1$	222	+	+
DL-Threonine		mm2	+	+
L-Tryptophan				–
DL-Tryptophan				–
L-Tyrosine				+
DL-Tyrosine				+
L-Valine	$P2_1$	2	+	–
D-Valine				+
DL-Valine	P1 or $P\bar{1}$	1 or $\bar{1}$	+ or –	–

Table 1 gives for each crystalline compound the spatial group and the corresponding crystalline class in the Hermann–Maugin notation as stated by Gurskaya[16], Derissen *et al.*[17], Harding and Long[18] and Albrecht *et al.*[19]. In the fourth column, a plus sign indicates a piezoelectric class; a minus, a non-piezoelectric one. The last column records our experimental results, a plus sign being assigned for the samples in which piezoelectricity has been identified. Glycine is a special case: it has three crystalline forms (Table 2). Piezoelectricity is detected in the powder[3,8,15], but not in single crystals, in agreement with Guibé's experiments (personal communication). Because the γ-form is the most stable at room temperature[16], it is reasonable to think that glycine powder is in the γ-form and single crystals are in the non-piezoelectric α-form.

Table 2. COMPARISON OF EXPERIMENTAL AND THEORETICAL PIEZOELECTRICITY FOR GLYCINE AND DL-METHIONINE

Amino-acid	Spatial group	Crystalline class	Theoretical piezo-electricity[16]	Experimental piezo-electricity
α-Glycine	$P2_1/n$	2/m	–	–
β-Glycine	$P2_1$	2	+	+ (β or γ)
γ-Glycine	$P3_1$ or $P3_2$	3	+	
α-DL-Methionine	$P2_1/a$	2/m	–	+ (α or β)
β-DL-Methionine	I2/a	2/m	–	

Our experimental results agree well with crystalline studies. In spite of the weakness of the piezoelectric resonances, it was generally possible to confirm this effect in those crystalline classes for which it would be expected. Recent crystallographic results[17,18] confirm our experiments. For DL-methionine, which crystallizes in two forms (Table 2), and DL-serine, experimental piezoelectricity is exhibited in contradiction with the findings on crystal structure. This discrepancy needs to be resolved. In about twenty cases—for lack of crystal data—it is impossible to make a comparison, but we believe our results will be of importance in the assignment of crystal structure. It is interesting to note that of the twenty L-amino-acids we have studied (glycine included), nineteen exhibit theoretical and/or experimental piezoelectricity.

"Evolution"—"Development"—Anatomical and Cerebral Features and the Pathological Consequences

We recently published papers in the oceanographic field which contained in their titles the words "development"[1], "evolution"[2], "triple junctions"[2] and "fingers"[3]. These key words were dispatched by computers to thousands of child psychiatrists, biologists, neurologists and medical practitioners. Hundreds have requested reprints. We are curious to know how many are going to request a reprint of the present communication on the same basis.

BIOLOGICAL SCIENCES

Prostaglandins—an Experiment

I am writing not about prostaglandins but about requests for reprints of a *Nature* article[1] about them. In the first two months after this was published, I received 615 reprint requests of which 53 per cent came from the USA or Canada. Thirty-eight per cent of these, and 16 per cent of those from other countries, bore the name of the sender only in typewritten or rubber-stamped form. Of the handwritten names, internal evidence suggested that many were not personal signatures.

This kind of experience is doubtless very common. How can one assess the probability that a rubber-stamped card (probably sent by a technician who has scanned *Current Contents* for key-words) indicates anything more than a general interest in a subject and a disinclination to go to the library ? The answer may partially be provided by the response to the present letter. Anyone who reads this is asked not to request a reprint.

Absorptivity and Quantum Yield of Bleaching in Bovine Visual Pigment$_{500}$

Visual pigments are conjugated proteins containing either retinal or 3-dehydroretinal as the chromophoric prosthetic group. The molar absorptivity (ε) of the pigments at their absorption maximum in the visible spectrum has been determined either by measuring the retinal or the apoprotein content in a given amount of visual pigment. Knowledge of the molar absorptivity of visual pigments is of practical importance because concentrations are most easily determined by spectrophotometric methods. In addition, this parameter has a theoretical interest in that it enables one to calculate the quantum yield (φ) of bleaching.

Wald and Brown[1] determined the amount of all-*trans* retinal oxime formed from a given amount of illuminated visual pigment after reaction with hydroxylamine and found an $\varepsilon_{500\text{ nm}}$ of 40,600, assuming one chromophore per molecule. A similar value was found by Shichi *et al.*[2] using a chemical determination of the retinal liberated from illuminated visual pigment. The determination[3] of the molar absorptivity ($\varepsilon_{500\text{ nm}}$), however, performed by measuring the amount of protein in purified samples of visual pigment, gave a value of 23,100. A new attempt was therefore made to determine the molar absorptivity of visual pigment by at least two different methods to find the cause of the disagreement.

Table 1. MOLAR ABSORPTIVITY OF BOVINE VISUAL PIGMENT$_{500}$ DETERMINED BY AMINO-ACID ANALYSIS

	$A_{500\text{ nm}}$	μmole protein	$\varepsilon_{500\text{ nm}}$
Sample I	0·417	0·01914	21,786
		0·01924	21,673
Sample II	0·350	0·01638	21,367
		0·01646	21,263
Average			21,524

Native visual pigment$_{500}$ was purified as the cetyltrimethylammonium bromide complex[3]. Duplicate samples of known absorptions obtained from two separately purified visual pigment$_{500}$ preparations were hydrolysed with 6 M HCl for 24 h at 110° in sealed, evacuated tubes and were then analysed on the amino-acid analyser. Assuming a molecular weight of 26,400 for the visual pigment apoprotein, the stable amino-acid residues aspartic acid, glutamic acid, glycine, alanine, leucine and phenylalanine were used to calculate the amount of protein present on the basis of the previously known composition[4]. Independent measurements in several laboratories have led to the conclusion that the molecular weight of visual pigment is indeed around 28,000 (refs. 2–4). The molar absorptivity of the sample could then be calculated in a direct way and the results are shown in Table 1.

Attempts were then made to determine the molar absorptivity as described by Shichi *et al.*[2], who determined the retinal content of visual pigment using the method of Futterman and Saslaw[5]. This method is based on the colorimetric reaction of the aldehyde group of retinal with thiobarbituric acid. Although excellent reproducibility and accuracy were obtained with standard all-*trans* retinal, only very erratic and nonreproducible results were obtained with visual pigment. The $\varepsilon_{500\text{ nm}}$ values determined by this method, using the same pigment samples as were used for amino-acid analysis, ranged from 35,000 to more than 50,000. The variability and low yield of the reaction probably arise because other amino groups of the protein compete for the potential aldehyde group of retinal, as was shown by Ball *et al.*[6] for a series of interactions between amino groups and retinal, and possibly as a result of other effects such as oxidation or reduction of the aldehyde group. All the competing reactions would tend to reduce the colour yield with thiobarbituric acid and thus produce an apparent increase in $\varepsilon_{500\text{ nm}}$. Similar considerations may apply to the oxime method[1] of determining the retinal content of visual pigment.

The photosensitivity of visual pigments is defined as the product of the molar absorptivity and the quantum yield of change (εφ). Dartnall *et al.*[7,8] found the photosensitivity of frog visual pigment to be 23,000 and Dartnall[9] later reported that the photosensitivity of a series of visual pigments ranges from 26,300 to 28,500. With the $\varepsilon_{500\text{ nm}}$ value obtained above and with the knowledge that the $\varepsilon_{500\text{ nm}}$ of bovine and frog visual pigment are practically identical[10], it is possible to calculate the quantum yield of bleaching as 1·07 to 1·32 depending on the value of photosensitivity chosen (φ = photosensitivity/ε). Because it seems improbable that the quantum yield is larger than 1·0 in this system, either the molar absorptivity reported here is somewhat too low or the calculated photosensitivity is somewhat too high, or both. Nevertheless, the conclusion derived from these experiments is that the quantum yield of visual pigment$_{500}$ bleaching is either 1·0 or very close to 1·0 and that $\varepsilon_{500\ \mathrm{nm}}$ is between 21,500 and 23,000.

Linkage of Retinal to Opsin and Absence of Phospholipids in Purified Frog Visual Pigment$_{500}$

VISUAL pigments are components of the membranous disks of the rod and cone outer segments of vertebrates[1]. The traditional picture of visual pigment$_{500}$ (rhodopsin) is a chromophore (retinal) bound to opsin through a Schiff base linkage[2,3]. A role has long been sought for the large quantities of phospholipids present in outer segment disks, however, and it has been proposed that, in native visual pigment, retinal is bound by a Schiff base linkage to phosphatidyl ethanolamine (PE) rather than to opsin[4-6]. When exposed to light, retinal is considered to migrate from PE to the ε-amino group of a lysine residue in opsin, but Heller[7] has found that purified visual pigment contains little or no phospholipid (< 2 per cent). The following experiments are intended to resolve this contradiction; we have used the recent observation that visual pigment in the outer segment disks is continually being renewed[8,9], to show that purified visual pigment contains no phospholipid.

Two groups of fourteen frogs (*Rana pipiens*) were injected intravenously with 8·3 μCi/g body weight of sodium ^{32}P-orthophosphate. Group 1 was killed three days after injection and group 2 six days after. The rod outer segments were prepared under dim red light by the method of Heller[7], and the final pellet from both groups was treated identically. One third of the rod outer segment pellet was extracted with cetyltrimethylammonium bromide and the visual pigment was purified in the dark on an agarose column[7,8]. The absorptivity of the effluent was monitored at 280 nm and 500 nm. Radioactivity in each tube was measured and corrected for decay and quenching. The results are shown in Figs. 1*a* and *b*. The remaining two-thirds of the pellet was exposed to light, homogenized in 2 : 1 chloroform–methanol mixture and used for extraction of total lipids. The residue was extracted successively with 5 ml. aliquots of the following solvents: chloroform–methanol, 2 : 1 (twice); ethanol (twice); chloroform–methanol–conc. HCl, 200 : 100 : 1 (twice); and chloroform–methanol, 2 : 1 (three times). The extracts were combined, taken to dryness and dissolved in 3 ml. of chloroform–methanol, 2 : 1. This solution was extracted three times with 2 ml. aliquots of 0·73 per cent NaCl. The organic phase was dried under nitrogen and then under vacuum overnight. The dried residue was weighed (Table 1) and dissolved in 2 ml. of chloroform. Phospholipids in the extract were separated by DEAE-cellulose chromatography[10]. The purity of the PE and phosphatidyl choline (PC) fractions was verified on thin layer chromatograms (silica gel G)[11]. Radioactivity on the strips was located using a chromatogram scanner. The PE and PC samples prepared by this method showed no contamination by other phospholipids, or by other radioactive compounds. The purified samples of PE and PC were taken to dryness under nitrogen and dissolved in 1 ml. of chloroform. Duplicate aliquots were taken for the measurement of radioactivity and for phosphorus analysis[12]. No inorganic orthophosphate was present in these phospholipid samples. After correction for decay and quenching, the specific activity (d.p.m./μmole P) of the phospholipid phosphorus could be calculated for the PE and PC. These results are shown in Table 1.

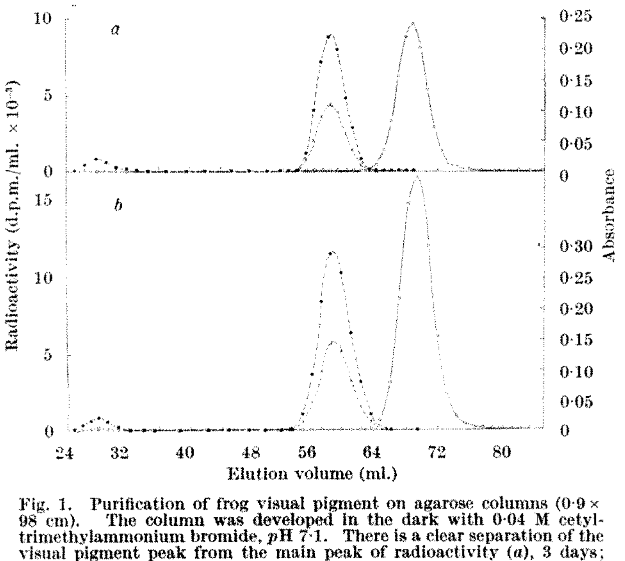

Fig. 1. Purification of frog visual pigment on agarose columns (0·9 × 98 cm). The column was developed in the dark with 0·04 M cetyltrimethylammonium bromide, *p*H 7·1. There is a clear separation of the visual pigment peak from the main peak of radioactivity (*a*), 3 days; (*b*), 6 days. ● - - - ●, A_{280}; × - - - ×, A_{500}; ○—○, d.p.m.

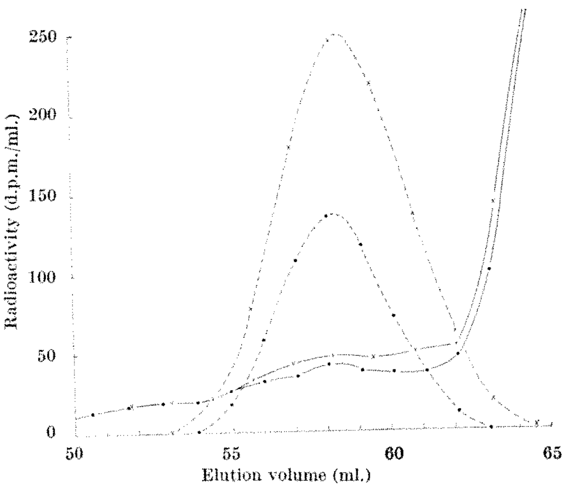

Fig. 2. Expanded scale plot of a portion of Fig. 1*a* and *b*, showing the comparison between observed d.p.m./ml. (———) and theoretical d.p.m./ml. (- - -) across the visual pigment peaks after agarose column purification. ●, Group 1; ×, group 2.

Figs. 1*a* and *b* show that agarose gel filtration completely separates the visual pigment and the main peak of radioactivity. The small amount of radioactive contamination of the visual pigment is shown in Fig. 2, and is discussed below.

From the known ε_{500} of frog visual pigment (23,100) (ref. 13) and the measured A_{500} nm of the purified visual

Table 1. SPECIFIC ACTIVITIES OF PE AND PC ISOLATED FROM FROG RETINAL ROD OUTER SEGMENTS

	Dry wt of total lipid	Specific activity (d.p.m./μmole P)	
		PE	PC
Group 1	7·85 mg	27,800	26,200
Group 2	8·13 mg	39,000	39,400

pigment fractions, it is possible to calculate the μmoles of visual pigment/ml. in each tube across the visual pigment peak (Figs. 1*a* and *b*). It has recently been directly demonstrated that one mole of retinal is bound per mole of visual pigment[14]. If retinal is bound to PE in native visual pigment, as proposed by Poincelot *et al.*[4], there must be a minimum of one mole of PE phosphorus/mole of visual pigment across the chromatographic peak. Because the specific activity of the PE phosphorus is known (Table 1), it is possible to calculate the theoretical d.p.m./ml. in each tube across the visual pigment peak.

In Fig. 2, elution profiles of the visual pigment isolated from both groups of frogs are plotted on an expanded scale to show the observed d.p.m./ml. across the respective visual pigment peaks and the theoretical d.p.m./ml. are plotted on the same scale. It can be seen that only 19 per cent (group 2) or 31 per cent (group 1) of the expected disintegrations are actually present in the visual pigment at the elution peaks: if the radioactivity found in the visual pigment fraction is not all due to PE, the discrepancy would be even greater. (Using 40,600 as the ε_{500} of frog visual pigment[15], then only 33 per cent (group 2) or 54 per cent (group 1) of the expected disintegrations are found.) To determine whether the low levels of radioactivity in the visual pigment were actually due to phospholipid, the tubes across the visual pigment peaks, from both groups of animals, were combined and lyophilized. The residue was exhaustively extracted for lipids, RNA and DNA[16]. The percentage of the total radioactivity extracted into each fraction was: lipid extract, 0 per cent; RNA extract, 12 per cent; DNA extract, 9 per cent; residue, 74 per cent.

The absorptivity of each nucleic acid extract was measured at 260 nm and 280 nm. Because these extracts showed no absorption at either wavelength, it is clear that the contaminating radioactivity was not caused by nucleic acids. The remaining 74 per cent of the radioactivity present in the residue is probably ^{32}P adsorbed onto the protein. Because no radioactivity was found in the lipid extract, it can be concluded that the small amount of radioactivity present in the purified visual pigment was not due to phospholipid.

It has been demonstrated that purified visual pigment contains no phospholipid and that retinal cannot be bound to PE in native visual pigment. The chromophore must therefore be bound covalently to opsin—probably to the ε-amino group of a lysine residue, as suggested by Bownds[2].

We thank Mr Dennis Muehlenbach for expert technical assistance. This investigation has been supported by a research grant from the National Institutes of Health, US Public Health Service, and a Fight-For-Sight grant-in-aid from the National Council to Combat Blindness, Inc., New York, NY.

Relation of Intracellular Ca^{2+} to Retention of K^+ by Liver Slices

CALCIUM ions are necessary for the maintenance of the normal, low permeability of cell plasma membranes[1-3]: if animal cells are incubated in media free of Ca^{2+} the passive permeability of the membranes increases, and the cells are unable to maintain their normal concentration gradients of K^+ and Na^+ (refs. 4, 5). Recent work has suggested, however, that a raised level of intracellular Ca^{2+} specifically increases the passive permeability of erythrocyte membranes to K^+. Liver cells possess an energy dependent mechanism which can bring about the net extrusion of Ca^{2+} that has accumulated during incubation at 1° C (refs. 7, 8). It was therefore of interest to examine the relationship between the lowering of intracellular Ca^{2+} thus produced and the accompanying recovery of the K^+ and Na^+ composition of the cells.

Liver slices were prepared from well fed, male albino rats and incubated for 90 min at 1° C in phosphate or bicarbonate buffered media. They were then transferred to Warburg manometric vessels which, after being flushed with O_2 or 95 per cent O_2–5 per cent CO_2, were placed in a bath maintained at 38° C. Slices were removed at intervals and their ionic contents determined by atomic absorption spectrophotometry (for further details, see refs. 8, 9). Results are related to the fat-free dry weight of the slices, and are expressed as mean ± *S.E.*

The time-course of the net, active movements of cations in slices incubated at 38° C in bicarbonate medium (Fig. 1) indicates that a net extrusion of Na^+ and Ca^{2+} began within the first sampling period (3 min) but, as noted previously[9,10], accumulation of K^+ was delayed by 10–15 min. In view of the coupling between Na^+ and K^+ transport in rat liver[9,11], the failure to observe an immediate K^+ accumulation seems to be the result of an inability of the cells to retain the K^+ transported inwards in exchange for Na^+, rather than a failure of the transport itself. There was a coincidence between the time at which the

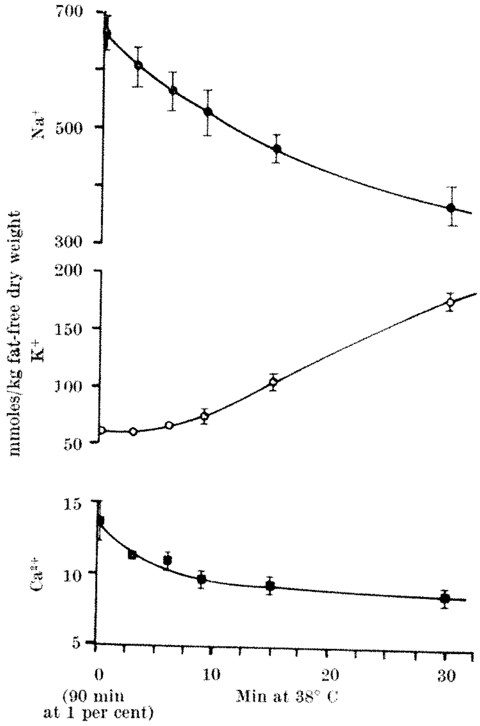

Fig. 1. Changes in cation content of liver slices during incubation at 38° C. Slices were incubated in bicarbonate medium at 1° C for 90 min, followed by incubation at 38° C for the times indicated. The medium contained (mM): Na^+ 161·5, K^+ 5·0, Ca^{2+} 1·3, Mg^{2+} 1·0, Cl^- 147·5, HCO_3^- 25·0, SO_4^{2-} 1·0, phosphate 2·0; it was gassed with 95 per cent O_2–5 per cent CO_2; *p*H was 7·4. Each point is the mean of five–seven observations.

net extrusion of Ca^{2+} was largely completed, and that at which net accumulation of K^+ started to occur. One possible explanation for this, which is suggested by Whittam's results[6], is that the initial high intracellular Ca^{2+} concentration was the cause of the failure of K^+ retention, K^+ becoming more efficiently retained as the Ca^{2+} concentration fell.

If this explanation is correct, the lag in K^+ accumulation should not be seen in slices which have been allowed to complete the extrusion of Ca^{2+} before the coupled Na^+–K^+ transport system is activated. It should be noted that the mechanisms for Ca^{2+} transport and for Na^+–K^+ transport seem to be independent in this tissue[8]. Slices were incubated at 1° C in K^+-free bicarbonate medium which was changed several times during the 90 min incubation to remove as much endogenous K^+ as possible from the system. To some flasks (controls), K^+ was tipped from the side-arms at the moment of being transferred to the bath at 38° C, to activate the Na^+–K^+ transport; its concentration in the medium was 5 mM. In other flasks (experimental), this transport was only activated by tipping K^+ after incubation at 38° C had proceeded for 20 min, that is, after Ca^{2+} extrusion was complete. Fig. 2 shows that the experimental slices accumulated a considerable amount of K^+ within 5 min after K^+ addition, and there was no indication of a lag period. At 10 min the net accumulation of intracellular K^+ in these slices (67 ± 14 mmoles/kg fat-free dry weight) was significantly higher than it was in the controls 10 min after the simultaneous addition of K^+ and start of incubation at 38° C (29 ± 2 mmoles/kg, $P < 0.05$; in calculating these values, an allowance was made for extracellular K^+ on the basis of the inulin-space measurements of Elshove and myself).

By contrast with these experiments, in which the tissue Ca^{2+} was lowered by active transport, the more drastic depletion of Ca^{2+} caused by incubation in a Ca^{2+}-free medium, especially with the addition of 2 mM EDTA, resulted in a failure of the liver slices to restore the maximal gradients of Na^+ and K^+ after much longer times (70 min) at 38° C (see also ref. 4). This effect must be largely the result of an increased passive permeability of the cells in the absence of medium Ca^{2+} (ref. 5).

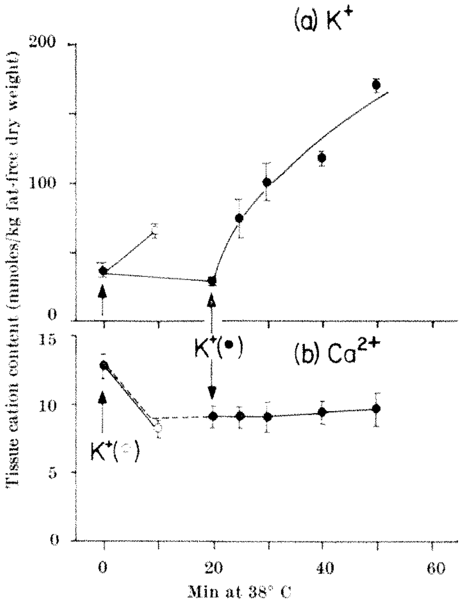

Fig. 2. Effect of K^+ addition on active movements of K^+ and Ca^{2+} in liver slices incubated at 38° C. Conditions as for Fig. 1, except that the incubation was carried out in K^+-free bicarbonate medium until the addition of K^+ (5 mM) at the times indicated by the arrows. Each point is the mean of six–eight observations. ○, K^+ added to medium after 0 min at 38° C; ●, K^+ added to medium after 20 min at 38° C.

The temporal relationship between Ca^{2+} extrusion and the onset of K^+ accumulation (Figs. 1 and 2) suggests that the initial failure to retain K^+ may be attributed in some way to the high intracellular Ca^{2+} concentration. This suggestion is further supported by the work of Judah and Ahmed[4], who found that the accumulation of K^+ in 20 min by slices recovering from pre-incubation in low-Na^+ media varied inversely as the concentration of Ca^{2+} in the pre-incubation medium (and so, presumably, as the initial intracellular Ca^{2+}). By contrast, however, the failure of K^+ retention in the presence of high intracellular Ca^{2+} does not result from the inhibition of the Na^+–K^+ transport mechanism by Ca^{2+}, for in the present work Na^+ extrusion at 38° C proceeded without a delay period. For the same reason, an inhibitory effect of Ca^{2+} on the energy supply for alkali-cation transport (for example, by uncoupling oxidative phosphorylation) can be excluded in these conditions (but see ref. 12). The effect of intracelluar Ca^{2+} would therefore seem to arise either from some action at a K^+-retaining site within the cell (for example, neutralization by Ca^{2+} of anionic binding sites for K^+), or from a Ca^{2+} induced increase in the passive permeability of the plasma membrane towards K^+ efflux (as indicated by Whittam[6]). The mechanism is not clear at present, but because a general deprivation of tissue Ca^{2+} (as in Table 1) leads to increased passive permeability, the Ca^{2+} the removal of which by active transport would result in a decreased passive permeability must be a rather specific fraction of the total cellular content of this cation.

Table 1. EFFECT OF Ca^{2+}-FREE MEDIUM ON THE CATION COMPOSITION OF RAT LIVER SLICES INCUBATED AT 38° C

Medium (mM)		Tissue content (mmoles/kg fat-free dry weight)					
		Ca^{2+}		K^+		Na^+	
Ca^{2+}	EDTA	1°	38°	1°	38°	1°	38°
1·3	0·0	13·5 ± 0·3 (8)	10·7 ± 0·5 (15)	73 ± 6	305 ± 5	939 ± 34	474 ± 19
0·0	0·0	—	2·6 ± 0·2 (8)	—	147 ± 17	—	606 ± 44
0·0	2·0	2·8 ± 0·5 (3)	1·6 ± 0·2 (8)	61 ± 6	106 ± 5	—	844 ± 22

The slices were incubated for 90 min at 1° C in phosphate buffered medium containing Ca^{2+} or EDTA as indicated. Vessels were gassed with O_2 before transfer to a bath at 38° C for a further 70 min incubation. The complete phosphate medium used in line 1 contained (mM): Na^+ 161·5, K^+ 5·0, Ca^{2+} 1·3, Mg^{2+} 1·0, Cl^- 151·5, SO_4^{2-} 1·0, phosphate (pH 7·4) 10·0. The number of experiments is indicated in parentheses.

I thank Dr B. Chance for his interest. The work was supported by a grant from the US Public Health Service.

NMR Investigation of Deuterated Collagen

KNOWLEDGE of the structures of biological macromolecules stems almost exclusively from X-ray diffraction studies. In conjunction with molecular models, the diffraction patterns may be used to assign the positions of atoms other than hydrogen, and ultimately their relative angular

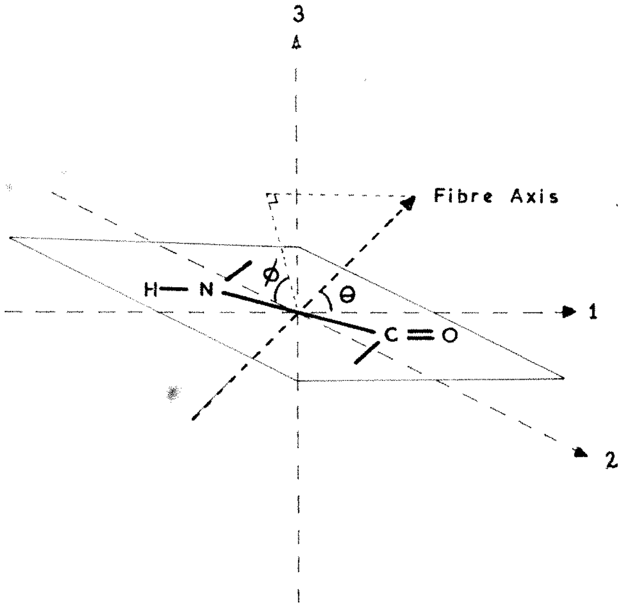

Fig. 1. The axis system for the planar peptide group and the definition of the spherical polar angles θ and φ.

spacing. We may describe the information as translational in character and this can only be interpreted in rotational, or angular, terms with the help of model building. Further, the assignment of any hydrogen bonds is not possible. We demonstrate here that the orientation of peptide groups may be determined relative to a fibre axis directly from nuclear magnetic resonance (NMR) measurements of the quadrupole couplings experienced by deuterium nuclei substituted for the peptide hydrogens. The couplings observed are sensitive to the type of hydrogen bond present and may become diagnostic for them.

When the electronic charge distribution around a spin 1 nucleus does not have spherical symmetry, the interaction between the nuclear quadrupole moment and the electric field gradients lifts the degeneracy of the $-1 \rightarrow 0$ and $0 \rightarrow 1$ transitions in the NMR spectrum. The Hamiltonian for this interaction is[1]:

$$\frac{(e^2 q_{zz}\, Q)}{4I\,(2I-1)}\,(3I_z^2 - I\,(I+1))$$

where e is the electronic charge, Q is the nuclear quadrupole moment and q_{zz} is the component of the field gradient tensor in the magnetic field direction. In the first order case, where the Zeeman interaction is much greater than the quadrupole one, this gives rise to a doublet in the NMR spectrum with a frequency splitting of $(3/2)e^2q_{zz}\,Q/h$, where h is Planck's constant. When the perturbation is expanded to second order, the doublet splitting does not alter, though the doublet components are slightly shifted. The field gradient tensor is traceless and of second rank. This means that q_{zz} can be expressed as

$$q_{zz} = q_{11}[\cos^2 \alpha_1 - \tfrac{1}{2}(1-\eta)\cos^2 \alpha_2 - \tfrac{1}{2}(1+\eta)\cos^2 \alpha_3]$$

where q_{11} is the quadrupole coupling constant in the 1-direction, α_n is the angle between the nth principal axis of the tensor and the z axis, and η is the asymmetry parameter—a measure of the departure of the tensor from axial symmetry about the 1 axis.

The essence of the application to fibrous proteins is that if the magnetic field direction is made coincident with the fibre axis, all equivalent spin 1 nuclei in the structure will give identical quadrupole splittings in the NMR spectrum. Deuterium has a spin of 1, and can be exchanged for hydrogen in the peptide groups quite easily. There are other easily exchangeable hydrogens in proteins, but they are usually well out in the residue side chains, and it will be assumed here that these have little regularity in their orientation. As a result, they will give a very weak background spectrum, out of which the relatively sharp doublet components from the deuteriums of the peptide groups will appear.

The problem now is to decide the magnitudes and directions of the principal components of the field gradient tensor for deuterium in a peptide group. The parameters chosen were those for the *trans* deuteriums in $^2H_4$-urea[2]. These are: $q_{11} = 210{\cdot}8$ kHz, $q_{22} = -90{\cdot}8$ kHz, $q_{33} = -120{\cdot}0$ kHz, that is $\eta = 0{\cdot}139$. The 1 axis is parallel to the C–O axis, the 3 axis is perpendicular to the plane of the peptide group, and the 2 axis is mutually perpendicular to these. This choice was considered to be justified because the field gradients are sensitive only to the charge distribution near the nucleus[3], which is expected to be very similar for urea and the peptide group.

The angles α_n can now be expressed in terms of spherical polar angles θ, φ, which are defined in Fig. 1. Thus $\cos \alpha_1 = \cos \theta$, $\cos \alpha_2 = \sin \theta \cdot \cos \varphi$, $\cos \alpha_3 = \sin \theta \cdot \sin \varphi$. In this way, the method gives the angles describing the orientation of the peptide group with respect to the fibre axis.

The measurement of the deuterium splittings alone does not give the complete information, because this corresponds to one function of two unknowns. A second piece of information that can be extracted from the deuterium spectrum is the linewidths of the doublet components. The linewidths of the components arising from magnetic dipolar coupling should be only of the order of about 1 kHz, but if the fibrous sample is not perfectly oriented, or if the fibre axis is not perfectly aligned with the magnetic field, the doublet components will be broadened. This is because in this case a distribution of q_{zz} values will be sampled, instead of a single value, for equivalent deuteriums. The extent of this broadening is proportional to

$$\left[\left(\frac{\mathrm{d}q_{zz}}{\mathrm{d}\theta}\right)_{\varphi}^2 + \left(\frac{\mathrm{d}q_{zz}}{\mathrm{d}\varphi}\right)_{\theta}^2\right]^{\frac{1}{2}}$$

A contour map of this function is given in Fig. 2, in terms of q_{11}/radian, for the field gradient tensor of the urea *trans* deuterium.

We performed the first measurements on an α-helix, because the geometry is well known and the spectra would be expected to provide a test of the above assumptions. Working from the coordinates of Fraser *et al.*[4], the orientation of the peptide groups (which are all equivalent) is given by: $\theta = 14{\cdot}1°$, $\varphi = 0°$. This gives a predicted splitting of 289·4 kHz.

The second molecule chosen for study was the collagen molecule. A number of proposals have been put forward for the secondary structure of collagen, the ones most

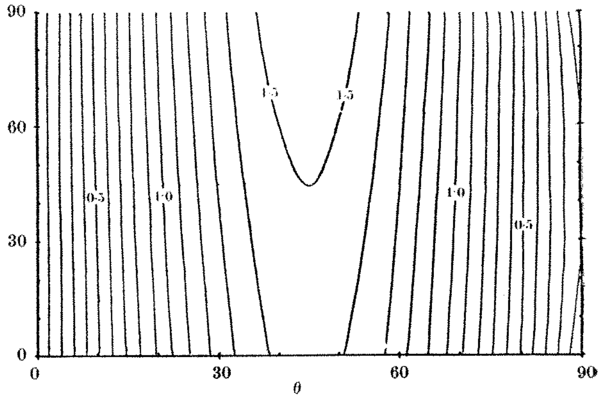

Fig. 2. A contour map showing the variation of the field gradient tensor gradient with θ and φ. The variation in the linewidth is directly proportional to this.

favoured being the collagen II structure[5], the Ramachandran two-bonded structure[6] and the new one-bonded structure[7], which we shall call collagen IIa. A complication now arises: in these three models there are three distinct hydrogen bonded states for the peptide hydrogens. One is the short hydrogen bond, as in the α-helix, which we shall designate state A. The second is a long hydrogen bond, state B. The third is where the deuterium is not formally hydrogen bonded in the structure, state C. For states B and C, there will almost certainly be an increase in the quadrupole coupling constant from the urea value, as is noticed with ^2H_2O when the hydrogen bonding is reduced[8]. We estimate the maximum possible limit of this increase to be 10 per cent for state B and 50 per cent for state C. Thus, working from the model coordinates, the predicted splittings and relative linewidths are as in Table 1.

Table 1. PREDICTED SPLITTINGS AND RELATIVE LINEWIDTHS

State	θ	φ	Splitting (kHz)	Relative broadening
		Collagen II		
C	71	36	102–153	0·90–1·35
C	81	30	136–204	0·47–0·71
A	83	53	157	0·39
		Ramachandran collagen		
B	83	53	157–173	0·39–0·43
B	86	39	151–166	0·25–0·27
C	73	38	107–161	0·84–1·26
		Collagen IIa		
C	70	42	101–152	0·97–1·45
C	70	27	91–137	0·96–1·44
B	85	38	147–162	0·29–0·32

The α-helix sample was a liquid crystalline solution of poly-γ-benzyl-L-glutamate of 300,000 molecular weight in dichloromethane. This phase is known to orient in strong magnetic fields such that the helices are parallel to the field[9]. The polypeptide had been deuterated previously by treatment with anhydrous ^{2}H-trifluoroacetic acid. The collagen sample was a cylindrical piece of well oriented bovine achilles tendon that had been immersed in acidified D_2O for three months. It was then removed and partially dried.

All spectra were recorded on a superconducting magnet spectrometer operating at about 50 kG (ref. 10). The frequency was swept by digitally advancing a frequency synthesizer, and simultaneously advancing a time-averaging computer, into which the spectrometer output was fed. Magnetic field modulation of about 2 G at 70 Hz was used, so the derivative of the spectrum was recorded. About 300 spectra were accumulated in the time-averaging computer on each run, because the signals were expected to be very weak.

The accumulated spectrum for the α-helix sample is shown in Fig. 3*a*. The poor phasing of the lines arises from problems with the bandwidth of the tuned probe assembly. In spite of this, however, it can be seen that there is a well defined doublet with a splitting of about 288·3 kHz. This is in very close agreement with the predicted value of 289·4 kHz, and we consider that this supports the identification of the field gradient tensor at the deuterium atom in the peptide group with that of the *trans* deuterium in urea, in magnitude, orientation and symmetry.

The accumulated spectrum for the collagen sample is shown in Fig. 3*b*, as the derivative of the dispersion mode. There is a doublet with fairly narrow components, with a splitting of about 157 kHz. In addition, there are two doublets with much wider components with splittings of about 117 kHz and 127 kHz. These doublets are consistent only with the collagen IIa model. Most, if not all, of the collagen molecule must therefore have this conformation.

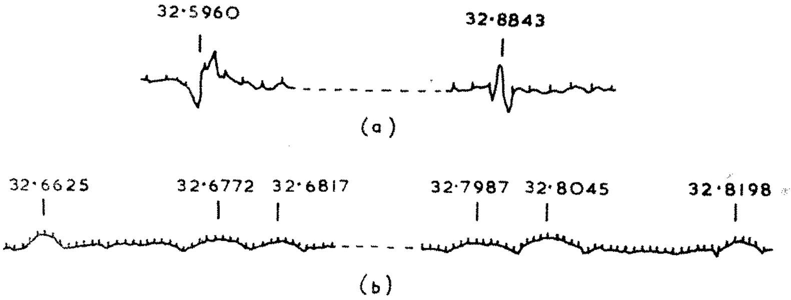

Fig. 3. The observed deuteron spectra of (*a*) the α-helical form of deuterated poly-γ-benzyl-L-glutamate and (*b*) deuterated bovine achilles tendon. In (*a*) the frequency markers are 1·6 kHz apart and in (*b*) 640 Hz apart. The measurements are in MHz.

This conclusion could not have been reached from the X-ray diffraction data and we suggest that the method may be particularly useful in investigating the structures of fibrous proteins which cannot be crystallized. The signal to noise ratio of the NMR spectra is unsatisfactory and work is in progress to improve this aspect of the technique. Attempts are also being made to use collagen samples with better orientations, in order to establish whether or not there is a second type of conformation present in collagen in small proportions.

We thank Professor R. E. Richards for the use of the spectrometer, Dr A. Miller for helpful discussions and Dr E. M. Bradbury for a generous gift of poly-γ-benzyl-L-glutamate. G. E. C. thanks the Medical Research Council for a maintenance award.

Anti-Rh Activity of Human γG4 Proteins

THE subclasses of human IgG, which differ antigenically and structurally, can also be differentiated by functional criteria. Analysis of functional similarities and differences among the immunoglobulins may provide some clue to the biological survival value of these proteins and to the evolutionary mechanisms which have determined the development and maintenance of the various forms.

Examples of functional differences among the subclasses of human IgG are: (1) γG1, γG3 and γG4 sensitize guinea-pig skin for passive, cutaneous anaphylaxis but γG2 does not[1]; (2) γG1 and γG3 interact well with complement components, but γG2 interacts poorly and γG4 does not interact at all[2]; and (3) the metabolic survival of γG3 molecules is shorter than that of the other three subclasses[3].

Consideration of antibody activity also suggests some functional differentiation: (1) antibodies to simple carbohydrate antigens tend to be of the γG2 subclass[4]; (2) all antibodies to coagulation factor VIII investigated so far

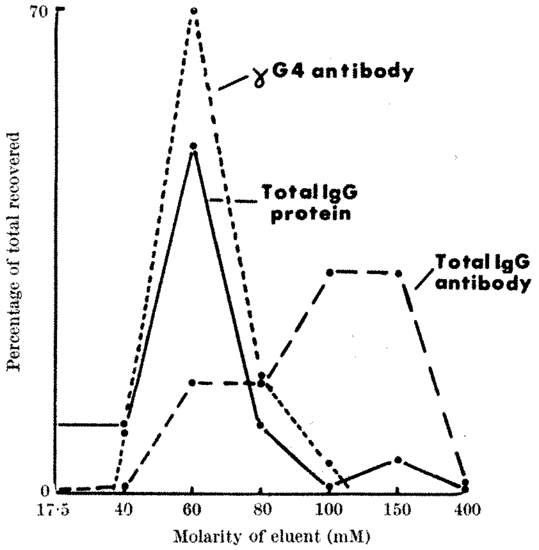

Fig. 1. Distribution of γG4 anti-D, total IgG anti-D and total IgG protein in CM–cellulose fractions of serum Ric.

are of the γG4 subclass[5]; and (3) Rh antibodies are of the γG1 and γG3 subclasses and lack the γG2 and γG4 subclasses[6].

In a search for additional examples of antibody specificity related to IgG subclass, human blood group antibodies were studied. Human red cells were sensitized with various blood group antibodies and the sensitized cells were then tested with antisera prepared against each of the four γG subclasses. Preliminary results strongly suggested that the anti Rh activity of two of the sera was attributable partly to γG4 molecules. γG4 anti Rh had not previously been described and further work was therefore undertaken.

Human sera containing antibodies with the following specificities and titres were tested: thirty-five examples of anti D, titres 64–4096 (no distinction was made between anti CD and anti D); 5 anti-c, titres 16–512 ; 1 anti e, titre 128; 11 anti K, titres 16–256; 1 anti Fy^a, titre 64; and 1 anti Jk^a, titre 64. Four volumes of undiluted serum were incubated with one volume of a 20 per cent suspension of appropriate red cells; after 1·5 h at 37° C, the cells were washed three times and tested, both with a potent anti human IgG and with an anti γG4 serum. The latter serum had been prepared by immunizing a rhesus monkey with a γG4 myeloma protein; the resulting antiserum was extensively absorbed with γG1, γG2 and γG3 myeloma proteins as well as hypogammaglobulinaemia serum. At dilutions greater than 1 in 10 (the optimal dilution was 1 in 800), this serum reacted specifically; that is, cells sensitized with only four of the thirty-five anti D sera were clearly agglutinated. Cells sensitized with three other anti D sera gave weakly positive reactions, while the remaining twenty-eight anti D sera and all other blood group antisera tested gave negative reactions. Among the antibodies which seemed to lack γG4 molecules were some particularly potent examples of anti D including the well known serum "Ripley"[7].

The specificity of the reactions observed with the "γG4 positive" sera was confirmed by inhibition tests; myeloma proteins of known γG subclass were added in a range of dilutions to the anti γG4 serum, and the mixtures were then tested with sensitized red cells. In tests with red cells sensitized with two of the "γG4-positive" anti D sera, the agglutination produced by the anti γG4 serum was completely inhibited by six different γG4 myeloma proteins at concentrations between 6×10^{-5} and $2·4 \times 10^{-4}$ g/100 ml. (slightly higher concentrations being required in tests with more strongly sensitized red cells). On the other hand, γG1, γG2 and γG3 myeloma proteins inhibited agglutination only at concentrations between 0·25 and 1·0 g/100 ml., that is, there was a thousand-fold difference between the inhibition produced by γG4 and by the other three subclasses (Table 1).

The anti Rh molecules in the four "γG4 positive" sera were not all of the γG4 subclass. When serial dilutions of the four "anti γG4 positive" sera were incubated with Rh positive red cells, and the cells were then washed and tested with anti IgG and anti γG4, respectively, three of the four titres with anti γG4 were much lower (Table 2).

Table 1. REACTIONS BETWEEN R_2R_2 CELLS SENSITIZED WITH A 1 IN 20 DILUTION OF SERUM Jud AND ANTI-γG4 SERUM (1 IN 400) TO WHICH AN EQUAL VOLUME OF VARIOUS CONCENTRATIONS OF DIFFERENT MYELOMA PROTEINS HAD BEEN ADDED

Myeloma protein		Concentrations of myeloma protein (g/100 ml.)						
Donor	Sub-class	1	0·25	6×10^{-2}	$2·4 \times 10^{-4}$	6×10^{-5}	$1·5 \times 10^{-5}$	Saline control

No	G4	–	–	–	–	–	+	+ +
Ro	G4	–	–	–	–	+	+ +	+ +

Table 2. COMPARISON OF TITRES OF THE FOUR "γG4 POSITIVE" ANTI D SERA WITH ANTI IgG (TOTAL) AND ANTI γG4

Donor	–IgG (total)	–γG4
Ric	1,024	128
Rus	256	128
Jud	4,096	32
Tri	1,024	16

Two of the "γG4 positive" sera were fractionated on carboxymethyl cellulose and it was found that the elution pattern of the γG4 molecules was different from that of the other anti D molecules in other anti Rh sera. Thus in a "typical" anti Rh serum the bulk of the IgG protein is eluted with the 0·06 M buffer, whereas most of the Rh antibodies are eluted with a buffer of higher molarity[8,9]. In serum "Ric", most of the γG4 antibody was eluted in the 0·06 M fraction with the bulk of the total IgG (Fig. 1). On the other hand, most of the antibody was eluted in the 0·1–0·15 M fractions, which sensitized red cells strongly to agglutination by anti-IgG but only weakly or not at all to agglutination by anti γG4, indicating that much of the antibody was of other subclasses—presumably γG1 or γG3, or both. The findings in serum "Jud" were similar.

Three additional anti D sera were tested after fractionation on CM–cellulose: "Avg", a potent serum which happened to contain both IgA and IgG anti D (ref. 10), "Jou", which had given doubtfully positive results with anti-γG4, and serum "Ripley" referred to previously. Not unexpectedly, all fractions from "Avg" were entirely negative, whereas the 0·06 and 0·08 M fractions from serum "Jou" gave a positive reaction with anti γG4 (which could be inhibited by diluted γG4 myeloma protein). An unexpected finding was that 0·06 M and 0·08 M fractions from serum "Rip" weakly sensitized red cells to anti γG4; these reactions were also inhibited by two γG4 myeloma proteins at a concentration of 10^{-3} g/100 ml.

Presumably it is easier to detect a low concentration of γG4 anti D molecules by sensitizing red cells with the 0·06 M or 0·08 M fractions, because in these fractions the ratio of γG4 to total γG is relatively high and competition for antigen sites with antibody molecules of other subclasses is reduced.

The demonstration of anti Rh antibodies of the γG4 subclass shows that with regard to antibody specificity there is less differentiation among the subclasses than was previously supposed. This type of antibody activity in γG4 molecules may have some biological significance because it has been reported that macrophages, derived from peripheral blood monocytes, have receptors for γG1 and γG3, but not γG2 or γG4 (ref. 11). Red cells sensitized with γG1 and γG3 molecules presumably can attach to monocytes and be ingested; those sensitized with γG2 and γG4 molecules cannot. The fate in the circulation of antibody-coated red cells that cannot be ingested by monocytes remains to be determined.

Identity of Chimpanzee with Human Fibrinopeptides

FIBRINOPEPTIDES, those portions of vertebrate fibrinogen molecules split off by thrombin during clotting, exhibit a very large degree of interspecific variability. The amino-acid sequences of these peptides have been determined for more than thirty different species of mammals, and the number of identified amino-acid replacements ranks the fibrinopeptides among the most variable polypeptide structures known. On the arbitrary scale developed by Dayhoff[1] these molecules have a variability index of 90, compared with values of 13 and 11 for the β and α chains of haemoglobin, and a score of 3 for cytochrome *c*. As a result of this propensity for rapid change, the fibrinopeptides are particularly useful for tracing phylogenetic relationships at the generic level.

Chimpanzees are the closest living evolutionary ancestors of man. It has previously been determined that the α and β chains of haemoglobin[2] and the cytochrome *c* molecules[1] of these creatures are identical with their respective human counterparts. We now report that the fibrinopeptides, in spite of their high degree of interspecific variability, are also identical in chimpanzees and humans.

Blood samples were collected from eight chimpanzees (four male and four female) into EDTA (1 mg/ml.). Approximately 100 ml. of the pooled plasma was used for the preparation of fibrinogen by previously described procedures[3]. After clotting (bovine thrombin), the fibrinopeptide mixture was isolated from the clot liquor by bulk adsorption on 'Dowex 50*X*2' (ref. 4). The peptide material was subsequently resolved into the constituent fibrinopeptides by gradient elution on a 1·2 × 40 cm 'Dowex 50*X*2' column (Fig. 1).

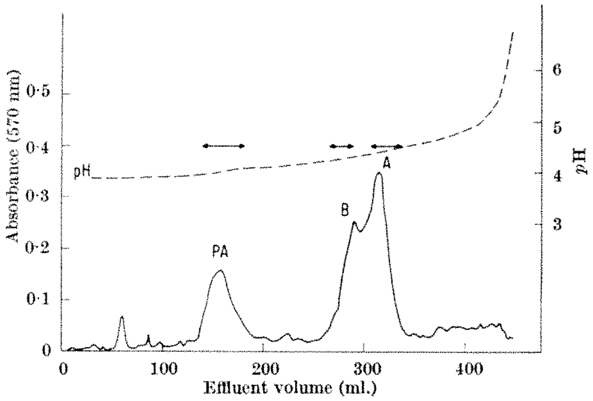

Fig. 1. Gradient chromatography of chimpanzee fibrinopeptides on 'Dowex 50*X*2'. Because the separation of A and B peptides was not complete, further purification had to be achieved by paper electrophoresis at *p*H 2.

Three different fibrinopeptides were isolated, eluting at identical *p*H positions as the corresponding human fibrinopeptide control sets, including a phosphorylated A peptide (eluting at *p*H 4·0), a B peptide (eluting at *p*H 4·3), and a non-phosphorylated A peptide (eluting at *p*H 4·4). The amino-acid compositions of these peptides were quantitatively determined after total acid hydrolysis and found to be indistinguishable from the corresponding human types, a large number of which had recently been analysed in this laboratory as part of a survey of individual human types (Table 1) (ref. 5). In addition, the chymotryptic peptides of the chimpanzee A and B fibrinopeptides were isolated and their amino-acid compositions found to be identical with human controls. In the case of the fibrinopeptide A, we isolated both the amino-terminal octapeptide produced by the chymotryptic attack on the phenylalanine residue at A9 (Fig. 2) and the overlapping nonapeptide produced by splitting at the leucine at A8.

Table 1. AMINO-ACID COMPOSITIONS OF CHIMPANZEE AND HUMAN FIBRINOPEPTIDES

Arginine	0·81	(1)	—	0·87	(1)	—	0	(1)	—
Total residues, *n*	16	16		16	16		14	14	

The values for the human controls are from ten sets of human fibrinopeptides isolated and resolved in the conditions used for isolation of the chimpanzee peptides. The human values are expressed as means and standard deviations, where $S.D. = \sqrt{\frac{\Sigma d^2}{n-1}}$. Arginine values were not measured in the human survey.

The corresponding carboxy-terminal fragments were also analysed. In the case of the B fibrinopeptide, the ninhydrin-negative ondecapeptide corresponding to the blocked amino-terminal peptide was isolated and analysed; the blocked amino-terminus leading to ninhydrin-negativity is attributable to terminal pyrrolidone carboxylic acid (PCA) residue. The carboxy-terminal tripeptide was also isolated and analysed. In all cases the electrophoretic mobilities (at *p*H 4·1) of the chymotryptic peptides

corresponded exactly with those of the human controls run simultaneously.

Finally, the proof of phosphorylation of the chimpanzee PA peptide was accomplished by enzymatic removal of the phosphate group by alkaline phosphatase (*Escherichia coli*) digestion followed by paper electrophoresis at *p*H 2. The change in peptide mobility after phosphate removal was exactly the same as observed for the human PA control, both types being converted into peptides with mobilities corresponding to non-phosphorylated A peptides.

Previously the fibrinopeptides from four old world species of monkeys had been characterized (rhesus, baboon, green monkey and drill)[1]. These have been found to differ from the human fibrinopeptides in five to eight of the thirty amino-acid positions compared. The identity of the chimpanzee and human fibrinopeptides re-emphasizes the extraordinarily close relationship of these two species on the molecular level. Recently Wilson and Sarich[6], on the basis of immunochemical and other molecular criteria, have argued that the time of divergence for these two species may have been as recent as 5 million years ago, in contrast to the 20–30 million year figures postulated by palaeontologists and others. Our data would support their contention, the chimpanzee and human—as judged by their fibrinopeptide structures—being more closely related than such pairs as horse–donkey, water buffalo–Cape buffalo, cat–lion, or dog–fox, all of which have at least one amino-acid difference in their fibrinopeptides[1]. On the other hand, sheep and goat (and ibex) have identical fibrinopeptides A and B, as do llama and vicuna[1]. The relatedness of chimpanzees and humans and the time of their divergence should be judged in the same context as the relationships proposed for each of the pairs compared here, all of which are thought to have diverged in Pleistocene or Recent times[7].

The chimpanzee blood used in these experiments was provided by Major Ralph F. Ziegler and his staff at the Aeromedical Research Laboratory, Holloman Air Force Base, New Mexico. We thank Miss Carol Glasgow for technical assistance. We also thank Drs Wilson and Sarich for sending us their manuscript before publication.

Separation of Isoenzymes by Zonal Centrifugation
